NATURE: APHORISMS BY GOETHE

NATURE! We are surrounded and embraced by her: powerless to separate ourselves from her, and powerless to penetrate beyond her.

Without asking, or warning, she snatches us up into her circling dance, and whirls us on until we are tired, and drop from her arms.

She is ever shaping new forms: what is, has never yet been; what has been, comes not again. Everything is new, and yet nought but the old.

We live in her midst and know her not. She is incessantly speaking to us, but betrays not her secret. We constantly act upon her, and yet have no power over her.

The one thing she seems to aim at is Individuality; yet she cares nothing for individuals. She is always building up and destroying; but her workshop is inaccessible.

Her life is in her children; but where is the mother? She is the only artist; working-up the most uniform material into utter opposites; arriving, without a trace of effort, at perfection, at the most exact precision, though always veiled under a certain softness.

Each of her works has an essence of its own; each of her phenomena a special characterisation: and yet their diversity is in unity.

She performs a play; we know not whether she sees it herself, and yet she acts for us, the lookers-on.

Incessant life, development, and movement are in her, but she advances not. She changes for ever and ever, and rests not a moment. Quietude is inconceivable to her, and she has laid her curse upon rest. She is firm. Her steps are measured, her exceptions rare, her laws unchangeable.

She has always thought and always thinks; though not as a man, but as Nature. She broods over an all-comprehending idea, which no searching can find out.

Mankind dwell in her and she in them. With all men she plays a game for love, and rejoices the more they win. With many, her moves are so hidden, that the game is over before they know it.

That which is most unnatural is still Nature; the stupidest philistinism has a touch of her genius. Whoso cannot see her everywhere, sees her nowhere rightly.

She loves herself, and her innumerable eyes and affections are fixed upon herself. She has divided herself that she may be her own delight. She causes an endless succession of new capacities for enjoyment to spring up, that her insatiable sympathy may be assuaged.

She rejoices in illusion. Whoso destroys it in himself and others, him she punishes with the sternest tyranny. Whoso follows her in faith, him she takes as a child to her bosom.

Her children are numberless. To none is she altogether miserly; but she has her favourites, on whom she squanders much, and for whom she makes great sacrifices. Over greatness she spreads her shield.

She tosses her creatures out of nothingness, and tells them not whence they came, nor whither they go. It is their business to run, she knows the road.

Her mechanism has few springs—but they never wear out, are always active and manifold.

The spectacle of Nature is always new, for she is always renewing the spectators. Life is her most exquisite invention; and death is her expert contrivance to get plenty of life.

She wraps man in darkness, and makes him for ever long for light. She creates him dependent upon the earth, dull and heavy; and yet is always shaking him until he attempts to soar above it.

She creates needs because she loves action. Wondrous! that she produces all this action so easily. Every need is a benefit, swiftly satisfied, swiftly renewed.—Every fresh want is a new source of pleasure, but she soon reaches an equilibrium.

Every instant she commences an immense journey, and every instant she has reached her goal.

She is vanity of vanities; but not to us, to whom she has made herself of the greatest importance. She allows every child to play tricks with her; every fool to have judgment upon her; thousands to walk stupidly over her and see nothing; and takes her pleasure and finds her account in them all.

We obey her laws even when we rebel against them; we work with her even when we desire to work against her.

She makes every gift a benefit by causing us to want it. She delays, that we may desire her; she hastens, that we may not weary of her.

She has neither language nor discourse; but she creates tongues and hearts, by which she feels and speaks.

Her crown is love. Through love alone dare we come near her. She separates all existences, and all tend to intermingle. She has isolated all things in order that all may approach one another. She holds a couple of draughts from the cup of love to be fair payment for the pains of a lifetime.

She is all things. She rewards herself and punishes herself; is her own joy and her own misery. She is rough and tender, lovely and hateful, powerless and omnipotent. She is an eternal present. Past and future are unknown to her. The present is her eternity. She is beneficent. I praise her and all her works. She is silent and wise.

No explanation is wrung from her; no present won from her, which she does not give freely. She is cunning, but for good ends; and it is best not to notice her tricks.

She is complete, but never finished. As she works now, so can she always work. Everyone sees her in his own fashion. She hides under a thousand names and phrases, and is always the same. She has brought me here and will also lead me away. I trust her. She may scold me, but she will not hate her work. It was not I who spoke of her. No! What is false and what is true, she has spoken it all. The fault, the merit, is all hers.

So far Goethe.

When my friend, the Editor of NATURE, asked me to write an opening article for his first number, there came into my mind this wonderful rhapsody on "Nature," which has been a delight to me from my youth up. It seemed to me that no more fitting preface could be put before a Journal, which aims to mirror the progress of that fashioning by Nature of a picture of herself, in the mind of man, which we call the progress of Science.

A translation, to be worth anything, should reproduce the words, the sense, and the form of the original. But when that original is Goethe's, it is hard indeed to obtain this ideal; harder still, perhaps, to know whether one has reached it, or only added another to the long list of those who have tried to put the great German poet into English, and failed.

Supposing, however, that critical judges are satisfied with the translation as such, there lies beyond them the chance of another reckoning with the British public, who dislike what they call "Pantheism" almost as much as I do, and who will certainly find this essay of the poet's terribly Pantheistic. In fact, Goethe himself almost admits that it is so. In a curious explanatory letter, addressed to Chancellor von Müller, under date May 26th, 1828, he writes:—

"This essay was sent to me a short time ago from amongst the papers of the ever-honoured Duchess Anna Amelia; it is written by a well-known hand, of which I was accustomed to avail myself in my affairs, in the year 1780, or thereabouts.

"I do not exactly remember having written these reflections, but they very well agree with the ideas which had at that time become developed in my mind. I might term the degree of insight which I had then attained, a comparative one, which was trying to express its tendency towards a not yet attained superlative.

"There is an obvious inclination to a sort of Pantheism, to the conception of an unfathomable, unconditional, humorously self-contradictory Being, underlying the phenomena of Nature; and it may pass as a jest, with a bitter truth in it."

Goethe says, that about the date of this composition of "Nature" he was chiefly occupied with comparative anatomy; and, in 1786, gave himself incredible trouble to get other people to take an interest in his discovery, that man has a intermaxillary bone. After that he went on to the metamorphosis of plants, and to the theory of the skull; and, at length, had the pleasure of seeing his work taken up by German naturalists. The letter ends thus:—

"If we consider the high achievements by which all the phenomena of Nature have been gradually linked together in the human mind; and then, once more, thoughtfully peruse the above essay, from which we started, we shall, not without a smile, compare that comparative, as I called it, with the superlative which we have now reached, and rejoice in the progress of fifty years."

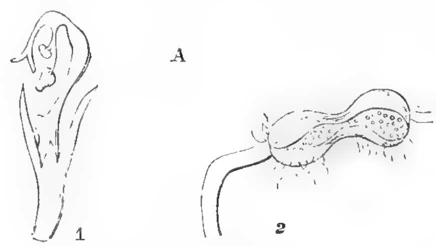
Forty years have passed since these words were written, and we look again, "not without a smile," on Goethe's superlative. But the road which led from his comparative to his superlative, has been diligently followed, until the notions which represented Goethe's superlative are now the commonplaces of science—and we have a super-superlative of our own.

When another half-century has passed, curious readers of the back numbers of NATURE will probably look on *our* best, "not without a smile;" and, it may be, that long after the theories of the philosophers whose achievements are recorded in these pages, are obsolete, the vision of the poet will remain as a truthful and efficient symbol of the wonder and the mystery of Nature. T. H. HUXLEY

ON THE FERTILISATION OF WINTER-FLOWERING PLANTS

THAT the stamens are the male organ of the flower, forming unitedly what the older writers called the "andrœcium," is a fact familiar not only to the scientific man, but to the ordinary observer. The earlier botanists formed the natural conclusion that the stamens and pistil in a flower are intended mutually to play the part of male and female organs to one another. Sprengel was the first to point out, about the year 1790, that in many plants the arrangement of the organs is such, that this mutual interchange of offices in the same flower is impossible; and more recently, Hildebrand in Germany, and Darwin in England, have investigated the very important part played by insects in the fertilisation of the pistil of one individual by the stamens of another individual of the same species. It is now generally admitted by botanists that cross-fertilisation is the rule rather than the exception. The various contrivances for ensuring it, to which Mr. Darwin has especially called the attention of botanists, are most beautiful and interesting; and the field thus opened out is one which, from its extent, importance, and interest, will amply repay the investigation of future observers. For this cross-fertilisation to take place, however, some foreign agency like that of insects is evidently necessary, for conveying the pollen from one flower to another. The question naturally occurs, How then is fertilisation accomplished in those plants which flower habitually in the winter, when the number of insects that can assist in it is at all events very small? I venture to offer the following notes as a sequel to Mr. Darwin's observations, and as illustrating a point which has not been elucidated by any investigations that have yet been recorded. I do not here refer to those flowers of which, in mild seasons, stray half-starved specimens may be found in December or January, and of which we are favoured with lists every year in the corners of newspapers, as evidence of "the extraordinary mildness of the season." I wish to call attention exclusively to those plants, of which we have a few in this country, whose normal time of flowering is almost the depth of winter, like the hazel-nut *Corylus avellana*, the butcher's broom *Ruscus aculeatus*, and the gorse *Ulex europæus;* and to that more numerous class which flower and fructify all through the year, almost regardless of season or temperature; among which may be mentioned the white and red dead-nettles *Lamium album* and *purpureum*, the *Veronica Buxbaumii*, the daisy, dandelion, and groundsel, the common spurge *Euphorbia peplus*, the shepherd's purse, and some others.

During the winter of 1868-69, I had the opportunity of making some observations on this class of plants; the result being that I found that, as a general rule, fertilisation, or at all events the discharge of the pollen by the anthers, takes place in the bud before the flower is opened, thus ensuring *self-fertilisation* under the most favourable circumstances, with complete protection from the weather, assisted, no doubt, by that rise of temperature which is known to take place in certain plants at the time of flowering. The dissection of a flower of *Lamium album* (Fig. A) gathered the last week in December, showed the stamens completely curved down and brought almost into contact with the bifid stigma, the pollen being at that time freely discharged from the anthers. A more complete contrivance for self-fertilisation than is here presented would be impossible. The same phenomena were observed in *Veronica Buxbaumii*, where the anthers are



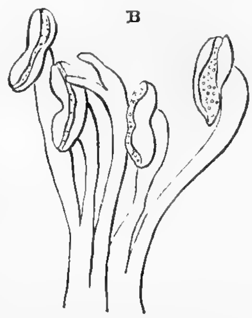
A. LAMIUM ALBUM.
1. Section of bud, calyx and corolla removed.
2. Stamen from bud, enlarged, discharging pollen.

almost in contact with the stigma before the opening of the flower, which occurs but seldom, *V. agrestis* and *polita*, the larger periwinkle *Vinca major*, the gorse, dandelion, groundsel, daisy, shepherd's purse, in which the four longer stamens appear to discharge their pollen in the bud, the two shorter ones not till a later period, *Lamium purpureum*, *Cardamine hirsuta*, and the chickweed *Stellaria media*, in which the flowers open only under the influence of bright sunshine. In nearly all these cases, abundance of fully-formed, seed-bearing capsules were observed in the specimens examined, all the observations being made between the 28th of December and the 20th of January.

In contrast with these was also examined a number of wild plants which had been tempted by the mild January to put forth a few wretched flowers at a very abnormal season, including the charlock *Sinapis arvensis*, wild thyme *Thymus serpyllum*, and fumitory *Fumaria officinalis;* in all of which instances was there not only no pollen discharged before the opening of the flower, but no seed was observed to be formed. An untimely specimen of the common garden bean *Faba vulgaris*, presented altogether different phenomena from its relative the gorse, the anthers not discharging their pollen till after the opening of the flower; and the same was observed in the case of the *Lamium Galeobdolon* or yellow archangel (Fig. B) gathered in April, notwithstanding its consanguinity to the dead-nettle.

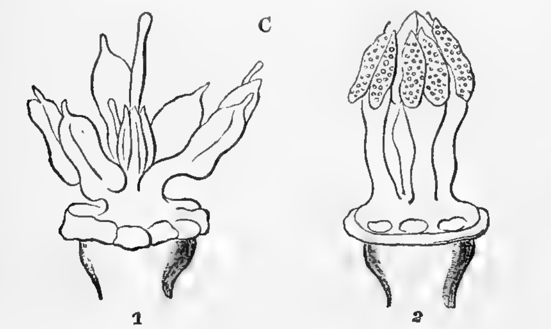
Another beautiful contrast to this arrangement is afforded by those plants which, though natives of warmer climates, continue to flower in our gardens in the depth of winter. An example of this class is furnished by the common yellow jasmine, *Jasminium nudiflorum*, from

China, which does not discharge its pollen till considerably after the opening of the flower, and which never fructifies in this country. But a more striking instance is found in the "allspice tree," the *Chimonanthus fragrans*, or *Calycanthus præcox* of gardeners, a native of Japan, which,



B. Lamium Galeobdolon.—Pistil and stamens from open flower; the latter discharging pollen.

flowering soon after Christmas, has yet the most perfect contrivance to prevent self-fertilisation (Fig. C). In a manner very similar to that which has been described in the case of *Parnassia palustris*,* the stamens, at first nearly horizontal, afterwards lengthen out, and rising up perpendicularly, completely cover up the pistil, and then discharge their pollen outwardly, so that none can possibly fall on the stigma. As a necessary consequence, fruit is never produced in this country; but may we not conjecture that in its native climate the *Chimonanthus* is



C. Chimonanthus fragrans

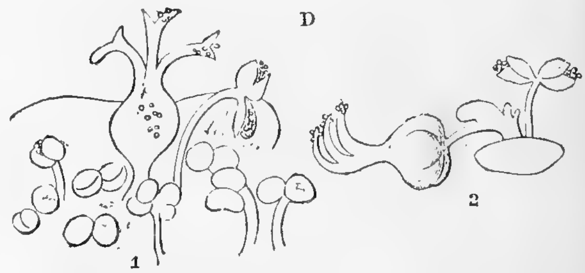
1. Early stage of flower, calyx and corolla removed.
2. Later stage, stamens surrounding the pistil, and discharging their pollen outwardly.

abundantly cross-fertilised by the agency of insects, attracted by its delicious scent, in a similar manner to our Grass of Parnassus?

The description detailed above cannot of course apply to those winter-flowering plants in which the male and female organs are produced on different flowers; but here we find commonly another provision for ensuring fertilisation. In the case of the hazel-nut the female flowers number from two to eight or ten in a bunch, each flower containing only a single ovule destined to ripen. To each bunch of female flowers belongs at least one catkin (often two or three) of male flowers, consisting of from 90 to 120 flowers, and each flower containing from three to eight anthers. The pollen is not discharged till the stigmas are fully developed, and the number of pollen-grains must be many thousand times in excess of what would be required were each grain to take effect. The arrangement in catkins also favours the scattering of the pollen by the least breath of wind, the reason probably why so many of the timber-trees in temperate climates, many of them flowering very early in the season, have their male inflorescence in this form.

* Journal of the Linnæan Society for 1868-69, Botany, p. 24.

The *Euphorbias* or spurges have flowers structurally unisexual, but which, for physiological purposes, may be regarded as bisexual, a single female being enclosed along with a large number of male flowers in a common envelope of involucral glands. Two species are commonly found flowering in the winter, and producing abundance of capsules, *E. peplus* and *helioscopia*. In both these species the pistil makes its appearance above the involucral glands considerably earlier than the bulk of the stamens (Fig. D).



D. Euphorbia helioscopia

1. Head of flowers opened, pistil and single stamen appearing above the involucral glands.
2. The same somewhat later, with the stigmas turned upwards.

A single one, however, of these latter organs was observed to protrude beyond the glands simultaneously, or nearly so, with the pistil, and to discharge its pollen freely on the stigmas, thus illustrating a kind of quasi-self-fertilisation. The remaining stamens do not discharge their pollen till a considerably later period, after the capsule belonging to the same set has attained a considerable size. In *E. helioscopia* the capsules are always entirely included within the cup-shaped bracts, and the stigmas are turned up at the extremity so as to receive the pollen freely from their own stamens. Now contrast with this the structure of *E. amygdaloides*, which does not flower before April (Fig. E). The heads of flowers which first open are entirely male, containing no female flower; in the hermaphrodite heads, which open subsequently, the stigmas are completely

E. Euphorbia amygdaloides.—Head of flower, pistil appearing above the involucral glands, all the stamens still undischarged.

exposed beyond the involucral glands long before any stamens protrude from the same glands. Here, therefore, complete cross-fertilisation takes place, the pollen from the first-opened male heads no doubt fertilising the stigma from the next-opened hermaphrodite heads, and so on. In this species the bracts are not cup-shaped, but nearly flat; the stigmas hang out very much farther than in *E. helioscopia;* and the styles are perfectly straight.

The above observations are very imperfect as a series, and I can only offer them as a contribution towards an investigation of the laws which govern the cross-fertilisation or self-fertilisation of winter-flowering plants. On communicating some of them to Mr. Darwin, he suggested that the self-fertilised flowers of *Lamium album,* and other similar plants, may possibly correspond to the well-known imperfect self-fertilised flowers of *Oxalis* and *Viola;* and that the flowers produced in the summer are cross-fertilised; a suggestion which I believe will be found correct.

In conclusion, I may make two observations. The time of flowering of our common plants given in our text-books is lamentably inexact; for the hazel, March and April for instance! and for the white dead-nettle, May and June! according to Babington. Great care also should be taken to examine the flowers the moment they are brought in-doors; as the heat of the room will often cause the anthers to discharge their pollen in an incredibly short space of time. This is especially the case with the grasses.

ALFRED W. BENNETT

PROTOPLASM AT THE ANTIPODES

THE Protoplasm excitement seems to have died away in a great measure in this country; and it is probably no loss to science that the matter has ceased to be a prevailing topic of conversation at dinner tables. We learn, however, from the Melbourne papers, that the arrival of the February number of the *Fortnightly Review* in the Australian colonies gave rise to an epidemic there of controversial science in a very alarming form. The description they give of the intellectual condition of Melbourne in June and July last, in fact, reminds us of that famous time at Constantinople, when a cobbler would not mend a pair of shoes until he had converted his customer from a Homousian to a Homoiousian, or *vice versâ.* The *Melbourne Daily Telegraph* is proud to think that a city which a few years back could only be stirred by a "Jumping Frog," is now agitated by proteinaceous theories; and this, too, in spite of the fact that they had previously been warned by the scientific correspondent of the *Melbourne Leader* of Mr. Huxley's gross ignorance and sensational superficiality. It is perfectly well known that at home here Mr. Huxley has been refuted many more times than there are copies of his article; but in Melbourne he was refuted over again afresh. We learn that the Rev. H. Higginson, "in a singularly able discourse at the Unitarian Church, tore the theory to shreds in a way"—reports the *Argus* with felicitous dubiety—"which showed the preacher to be as keen a humorist as he is a subtle logician." So able was the discourse, and so humorous, that it was repeated shortly afterwards as a lecture at the Mechanics' Institute. Here, however, the lecturer stated that it was a mistake to suppose that he had in the sermon either torn the theory to shreds or treated it in a humorous way; and the report of the lecture lends great support to the statement.

It may be perhaps gratifying to Mr. Huxley, to think that he has stirred men's minds in a place which was almost a *terra incognita* when the unknown young assistant-surgeon of the *Rattlesnake* looked upon it; but the papers tell us that a reprint of the *Fortnightly* article has been the first instance of infringement of copyright in that colony; and when the learned anatomist was speaking at Edinburgh he probably little thought that materialism would take its revenge on him by producing the following exercise in applied Biology :—

THE PHYSICAL BASIS OF LIFE.

Huxley's celebrated Essay on this subject is lectured on daily, by

WILLIAM BARTON,

who has made the matter a life study. It is also illustrated daily at his tables, where the "physical basis" can be laid in from 11 to 3, in the best cooked and most varied

HOT LUNCHEON

in the city.

The first feeling which comes to the mind after such things as these is an unbounded belief in the wisdom of those old teachers who kept esoteric and exoteric doctrines wide apart, and who laid bare the workings of their minds to trusted scholars only, and never to the vulgar gaze. We begin fervently to wish that our illustrious biologist had not, by the dress and mode of his lecture, so laid great biological truths before the public as to excite those especially ignorant of the science of life to try and trample them under foot, and then leave them for a vulgar tavern-keeper to hang up for a sign.

Second—better—thoughts, however, remind us that men of science work not for themselves, or for their scientific fellows, but for mankind; and that only mischief can come of it if they whose business it is to ask Nature her secrets are hindered from telling the world all that they think they hear. It is impossible to separate science from other knowledge and from daily life: all new discoveries especially must have ties with every part of our nature. It is not the business of the biologist to enforce on others what he believes to be the consequences of his biological discoveries; but it is certainly not his duty to withhold his facts from the common people because of the results which he thinks will follow.

And in regard to Australia in particular, we have this reflection, that the plough is needful for the seed; heavy land wants well turning up. There are not wanting signs that a national character is beginning to form among the inhabitants of that country; and we trust that scientific zeal will be one of its chief features. We hope that science even in a controversial form will never again give way in Melbourne to the vain delights of the "Jumping Frog;" and that the protoplasm which Mr. William Barton so admirably cooks will reappear in the nerve cells of Australian brains, and give rise to that love of truth, apart from gold or gain, which is the "moral" basis of "national" life. We may add that we hope not without confidence; for a bright example of conscientious truthfulness appeared in the midst of this small biological tempest. Many of our readers may remember the abundant fervour with which Prof. Halford, some years since, attacked Mr. Huxley's "Man's Place in Nature." At the end of Mr. Higginson's lecture the talented Melbourne anatomist courageously told the meeting, that he had seen reason to change his opinions. Every one here will rejoice to receive from the Antipodes a lesson of self-denial and moral daring, not too common amongst ourselves.

THE RECENT TOTAL ECLIPSE OF THE SUN

IF our American cousins in general hesitate to visit our little island, lest, as some of them have put it, they should fall over the edge; those more astronomically inclined may very fairly decline, on the ground that it is a spot where the sun steadily refuses to be eclipsed. This is the more tantalising, because the Americans have just observed their third eclipse this century, and already I have been invited to another, which will be visible in Colorado, four days' journey from Boston (I suppose I am right in reckoning from Boston?) on July 29, 1878.

Thanks to the accounts in *Silliman's Journal* and the *Philosophical Magazine*, and to the kindness of Professors Winlock and Morton, who have sent me some exquisite photographs, I have a sufficient idea of the observations of this third eclipse, which happened on the 7th of August last, to make me anxious to know very much more about them—an idea sufficient also, I think, to justify some remarks here on what we already know.

A few words are necessary to show the work that had to be done.

An eclipse of the sun, so beautiful and yet so terrible to the mass of mankind, is of especial value to the astronomer, because at such times the dark body of the moon, far outside our atmosphere, cuts off the sun's light from it, and round the place occupied by the moon and moon-eclipsed sun there is therefore none of the glare which we usually see—a glare caused by the reflection of the sun's light by our atmosphere. If, then, there were anything surrounding the sun ordinarily hidden from us by this glare, we ought to see it during eclipses.

In point of fact, strange things are seen. There is a strange halo of pearly light visible, called the corona, and there are strange red things, which have been called red flames or red prominences, visible nearer the edge of the moon—or of the sun which lies behind it.

Now, although we might, as I have pointed out, have these things revealed to us during eclipses if they belonged to the sun, it does not follow that they belong to the sun because we see them. Halley, a century and a half ago, was, I believe, the first person to insist that they were appearances due to the moon's atmosphere, and it is only within the last decade that modern science has shown to everybody's satisfaction—by photographing them, and showing that they were eclipsed as the sun was eclipsed, and did not travel with the moon—that the red prominences really do belong to the sun.

The evidence, with regard to the corona, was not quite so clear; but I do not think I shall be contradicted when I say, that prior to the Indian eclipse last year the general notion was that the corona was nothing more nor less than the atmosphere of the sun, and that the prominences were things floating in that atmosphere.

While astronomers had thus been slowly feeling their way, the labours of Wollaston, Herschel, Fox Talbot, Wheatstone, Kirchhoff, and Bunsen, were providing them with an instrument of tremendous power, which was to expand their knowledge with a suddenness almost startling, and give them previously undreamt-of powers of research. I allude to the spectroscope, which was first successfully used to examine the red flames during the eclipse of last year. That the red flames were composed of hydrogen, and that the spectroscope enabled us to study them day by day, were facts acquired to science independently by two observers many thousand miles apart.

The red flames were "settled," then, to a certain extent; but what about the corona?

After I had been at work for some time on the new method of observing the red flames, and after Dr. Frankland and myself had very carefully studied the hydrogen spectrum under previously untried conditions, we came to the conclusion that the spectroscopic evidence brought forward, both in the observatory and in the laboratory, was against any such extensive atmosphere as the corona had been imagined to indicate; and we communicated our conclusion to the Royal Society. Since that time, I confess, the conviction that the corona is nothing else than an effect due to the passage of sunlight through our own atmosphere near the moon's place has been growing stronger and stronger; but there was always this consideration to be borne in mind, namely, that as the spectroscopic evidence depends mainly upon the brilliancy of the lines, that evidence was in a certain sense negative only, as the glare might defeat the spectroscope with an uneclipsed sun in the coronal regions, where the temperature and pressure are lower than in the red-flame region.

The great point to be settled then, in America, was, What is the corona? and there were many less ones. For instance, by sweeping round the sun with the spectroscope, both before and after the eclipse, and observing the prominences with the telescope merely during the eclipse, we

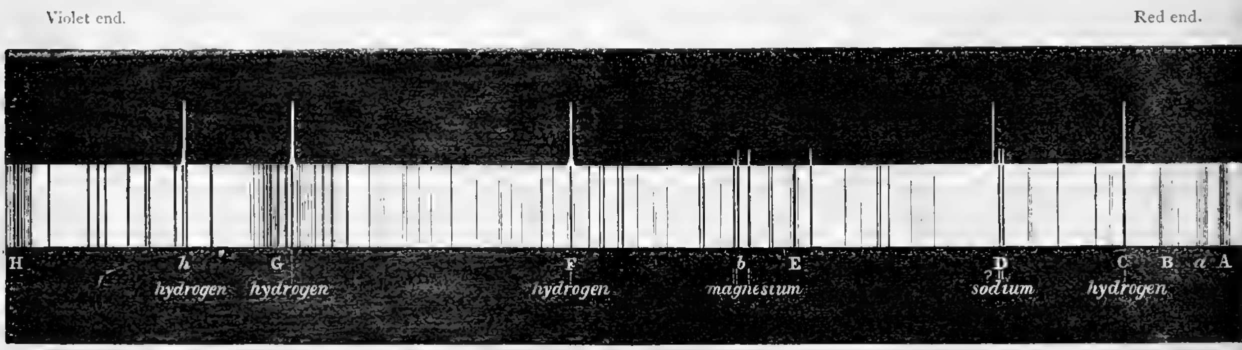


Fig. 1.—Showing the solar spectrum, with the principal Fraunhofer lines, and above it the bright-line spectrum of a prominence containing magnesium, sodium, and iron vapour at its base.

should get a sort of key to the strange cypher band called the spectrum, which might prove of inestimable value, not only in the future, but in a proper understanding of all the telescopic observations of the past. We should, in fact, be thus able to translate the language of the spectroscope. Again, by observing the spectrum of the same prominence both before and during, or during and after the eclipse, the effect of the glare on the visibility of the lines could be determined—but I confess I should not like to be the observer charged with such a task.

What, then, is the evidence furnished by the American observers on the nature of the corona? It is *bizarre* and puzzling to the last degree! The most definite statement on the subject is, that it is nothing more nor less than a *permanent solar aurora!* the announcement being founded on the fact, that three bright lines remained visible after the image of a prominence had been moved away from the slit, and that one (if not all) of these lines is coincident with a line (or lines) noticed in the spectrum of the aurora borealis by Professor Winloch.

Now it so happens that among the lines which I have observed up to the present time—some forty in number—this line is among those which I have most frequently recorded: it is, in fact, the first iron line which makes its appearance in the part of the spectrum I generally study when the iron vapour is thrown into the chromosphere. Hence I think that I should always see it if the corona were a permanent solar aurora, and gave out this as its brightest line; and on this ground alone I should hesitate to regard the question as settled, were the new hypothesis less startling than it is. The position of the line is approximately shown in the woodcut (Fig. 1) near E, together with the other lines more frequently seen.

It is only fair, however, to Professor Young, to whom is due this important observation, to add that Professor Harkness also declares for one bright line in the spectrum of the corona, but at the same time he, Professor Pickering, and indeed others, state its spectrum to be also continuous, a remark hard to understand unless we suppose the slit to have been wide, and the light faint, in either of which cases final conclusions can hardly be drawn either way.

So much, then, for the spectroscopic evidence with which we are at present acquainted on the most important point. The results of the other attacks on the same point are equally curious and perplexing. Formerly, a favourite argument has been that because the light of the corona is polarised; therefore it is solar. The American observers state that the light is *not* polarised—a conclusion, as M. Faye has well put it, "very embarrassing for Science." Further,—stranger still if possible,—it is stated that another line of inquiry goes to show that, after all, Halley may be right, and that the corona may really be due to a lunar atmosphere.

I think I have said enough to show that the question of the corona is by no means settled, and that the new method has by no means superseded the necessity of carefully studying eclipses; in fact, their observation has become of much greater importance than before; and I earnestly hope that all future eclipses in the civilised area in the old world will be observed with as great earnestness as the last one was in the new. Certainly, never before was an eclipsed sun so thoroughly tortured with all the instruments of Science. Several hundred photographs were taken, with a perfection of finish which may be gathered from the accompanying reproduction of one of them.

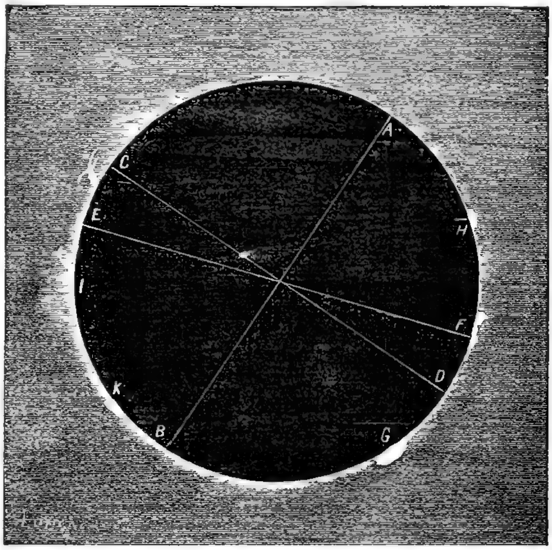

FIG. 2.—Copy of a photograph of the Eclipse of August 7, obtained by Professor Morton's party

The Government, the Railway and other companies, and private persons threw themselves into the work with marvellous earnestness and skill; and the result was that the line of totality was almost one continuous observatory, from the Pacific to the Atlantic. We read in *Silliman's Journal*, "There seems to have been scarcely a town of any considerable magnitude along the entire line, which was not garrisoned by observers, having some special astronomical problem in view." This was as it should have been, and the American Government and men of science must be congratulated on the noble example they have shown to us, and the food for future thought and work they have accumulated.

J. NORMAN LOCKYER

Since writing the above, I find the following independent testimony in favour of Dr. Frankland's and my own notion of the corona in the *Astronomische Nachrichten*, from the pen of Dr. Gould. He says:—"Its form varied continually, and I obtained drawings for three epochs at intervals of one minute. It was very irregular in form, and in no apparent relation with the protuberances on the sun, or the position of the moon. Indeed, there were many phenomena which would almost lead to the belief that it was an atmospheric rather than a cosmical phenomenon. One of the beams was at least 30′ long."

MADSEN'S DANISH ANTIQUITIES

Antiquités préhistoriques du Danemarck. By M. Madsen. Folio, pp. 19, with 45 engraved plates, some coloured. Price 36*s*. (London: Williams and Norgate.)

THIS work contains forty-five carefully executed plates of Danish Antiquities belonging to the Stone age. The first represents the Shellmound of Fannerup; a difficult subject, very faithfully rendered, as the present writer can testify. The three following plates give the common and characteristic objects of the Shellmounds. Then follow ten plates devoted to tumuli and dolmens. These are admirably executed, those of the great chambered tumulus at Uby being particularly successful. Plates xv. to xx. give certain remarkable "finds." These are very interesting, 50 objects discovered together being more instructive than 500 found separately. On the remaining plates are represented the most characteristic Danish forms, as well as many unique specimens. The work is devoted to the Stone age (the Bronze age portion, though commenced, not being yet completed), but it must not be supposed that all the specimens of stone implements here figured necessarily belong to the Stone age, although the great majority no doubt do so. It cannot, however, be too often repeated that many stone implements were in use during the Bronze age.

Everyone looking even cursorily at these plates must be struck by the excellence of the Danish flint, and the wonderful mastery which had been acquired over it. The daggers, for instance, represented in Pl. xxxv. are extraordinary instances of skill in flint chipping, and it must be confessed that such masterpieces could hardly be found in any country but Denmark.

It will be observed also that all the specimens figured belong, or may have belonged, to the Neolithic or second Stone period; there is not in the whole series, nor I believe is there in any of the great Danish museums, a single specimen of the characteristic Paleolithic forms. The rarity of the reindeer and of the mammoth renders this still more significant. We suppose that no one could look through these plates and yet retain any doubts as to the important part played by stone, and especially flint implements, in ancient times; though we must confess that we once showed our collection to a lady, who remained incredulous almost to the last, until we came to a drawer containing a roedeer's horn, which she at once said was evidently of human workmanship, and showed much skill.

The letterpress attached to the plates is confined to twenty pages, of which nine contain an introduction, the rest giving descriptions of the plates. It would, we admit, have been scarcely worth while to describe each specimen figured, but we regret that, excepting as regards the first few plates, no information is given as to the localities in, and the circumstances under, which they were discovered.

The introduction represents very fairly the general opinion of Danish archæologists, and with it we in the main concur. M. Madsen points out that the large, chambered, tumuli never contain metal, and, like Steenstrup, he doubts whether during that period the inhabitants of Denmark had any other domestic animal than the dog. No doubt some modern races, for instance the Polynesians, present this condition; but then their islands contained no cattle or sheep. It is, we think, very improbable that a people capable of such considerable constructions as the chambered tumuli, would not have tamed the wild cattle of the country.

Neither can we agree with M. Madsen and the Danish antiquaries in fixing the commencement of the Danish Iron age so late as the third century. We know that in southern Europe the use of iron commenced several hundred years earlier, and the great similarity of the bronze weapons all over Europe indicates clearly, we think, that they belonged to one and the same period. We cannot but think that the use of iron, when once discovered, would have spread rapidly over Europe, though it would, no doubt, have remained scarce in a comparatively poor country, as Denmark then was.

Lest our readers should suppose that a book containing more than forty beautifully executed plates must necessarily be very expensive, we may mention that the price is only *1l. 16s.* We heartily thank M. Madsen for this valuable addition to our Archæological Libraries.—JOHN LUBBOCK

NEWMAN'S BRITISH MOTHS

An Illustrated Natural History of British Moths. By Edward Newman, F.L.S. F.Z.S. &c. Large 8vo. pp. 486. (London: W. Tweedie.)

A HUNDRED years ago, or perhaps even less, a man who displayed a fondness for collecting insects was commonly regarded as a weak-minded individual, whose power of managing his own affairs, although it might in charity be conceded by his neighbours, was at least somewhat doubtful. To use the old Scotch phrase, he was supposed to have "a Bee in his bonnet," because he liked to have a Butterfly under his eyes.

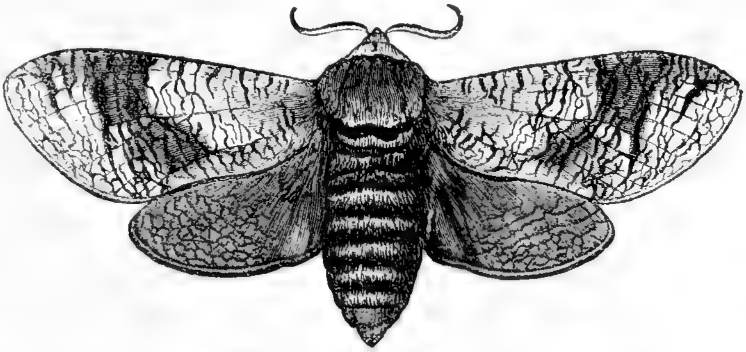
In the present day, although many people may be found who cannot see the use of such pursuits, one runs no risk of a commission *de lunatico*, on account of a predilection for moths or beetles; and if we may judge from the articles provided for the delectation of the multitude in our popular journals, natural history subjects, including entomology, form a not unattractive portion of their bill of fare.

The fact is, that the *cacoëthes colligendi* is one of the commonest affections of humanity, and there are few forms of the disease more harmless than the entomological one. Pictures and statues, books, prints and old china, call for a very considerable expenditure of hard cash, if it is desired to form ever so small a collection of any of them; but the insect-collector generally brings his treasures together by the labour of his own hands, and his boxes and pins do not cost much. Moreover, the collector of insects can hardly avoid learning something of the structure and habits of the objects of his pursuit—a knowledge which must have a favourable effect upon his own mind, and may frequently enable him to be serviceable to his neighbours.

Mr. Newman's "History of British Moths," which is now completed so far as the larger forms are concerned, is admirably adapted to favour these desirable objects; it not only furnishes good descriptions of the British species of moths, but gives an account of their habits in all stages of their existence. This book, which forms a handsome octavo volume, will be welcomed with enthusiasm by numbers of young entomologists in all parts of the country, as it gives them, in a convenient and intelligible form, pretty nearly all that can be told about the great group of insects of which it treats. It has another claim upon their attention also in the admirably executed woodcuts with which it is illustrated. Mr. Newman has given figures of every species, in many cases of both sexes of the species, and sometimes of their most prominent varieties, and these figures, although from their nature they are only in black and white, have been so carefully drawn, and so admirably cut, that the want of colour is hardly felt.

We reproduce here two of the cuts, which will show how effective the illustrations are. To the country entomologist working at a distance from any library, whence he can obtain the expensive illustrated works in which these insects are represented on coloured plates, these figures, accompanied as they are by good descriptions, will prove an invaluable boon; and we can only hope that Mr. Newman's book, the result of years of study, may meet with the success which it so well deserves.

W. S. DALLAS



THE GOAT MOTH (*Cossus ligniperda*)

THE MERVEILLE DU JOUR (*Agriopis aprilina*)

OUR BOOK SHELF

Text Book of Botany.—*Lehrbuch der Botanik für Gymnasien, Realschulen, &c.* By Dr. Otto W. Thomé. 1 vol. 8vo. 358 pp., with 621 woodcuts. Price 3*s.* (Brunswick, 1869.)

DR. THOMÉ'S name is new to us. He is a teacher in what we may call the Upper Grammar School at Cologne. Because he has not published original observations it does not follow that he should be a bad teacher. Rather, indeed, this is a point in his favour; for original observers, unless they be men of wide grasp of mind, or of great experience, are apt to ride special hobbies too far, and to be very unfair and crotchety.

A cursory inspection of this book leaves a favourable impression. It is German, of course, and the first chapter is entitled *Die Zelle als Individuum*, but so far as we can judge it is a handy book for a beginner, and if not all pure milk, it does not seem very badly diluted: much cream now-a-days it is hardly fair to look for. It is very copiously illustrated; the cuts by no means all original, and not a few borrowed from this side the Channel, but none the less well adapted to their purpose. D. O.

The Retardation of the Beat of the Heart.—*Das Hemmungsnervensystem des Herzens.* By Adolf Bernhard Meyer. (Berlin, 1869. London: Williams and Norgate.)

A CRITICAL and experimental inquiry into the inhibitory action of the pneumogastric nerve on the beat of the heart. The chief features of the experimental investigation are—first, the extension of the facts of inhibition to many animals (chiefly reptiles) not hitherto specially examined in reference to this point. Curiously enough, in *Emys lutaria* the left pneumogastric is inert; unfortunately Dr. Meyer has not worked out the cause of this singularity. Second, the author brings experiments to show that the effect of stimulation on the pneumogastric may be kept up for a very long time—more than an hour. In frogs the effect may be carried as far as complete stoppage for this time; in mammals as far as retardation only of the beat. M. F.

Exotic Lepidoptera.—*Lepidoptera Exotica; or, Descriptions and Illustrations of Exotic Lepidoptera.* By A. G. Butler, F.L.S., &c. (London: E. W. Janson.)

MR. BUTLER, who is well known as an ardent and careful student of the diurnal Lepidoptera, has undertaken, in conjunction with Mr. Janson as publisher, what will no doubt prove a very valuable and beautiful work. Many new species of Lepidoptera have been described—by Mr. Butler himself amongst others—without any figure: this practice is exceedingly inconvenient to those who attempt to identify species; and though, as Mr. Butler observes, it enables those who adopt it to "call the beautiful their own" to a larger extent than if they had to wait for figures, it is nevertheless a reprehensible proceeding, and has afflicted the conscience of one at least who has been guilty of it. Mr. Butler is a very skilful artist, and evidently an intense admirer of the lovely colours and forms of the insects he deals with. Consequently it is a matter for congratulation that he has undertaken to make up for the shortcomings of past times, and intends to bring out once a quarter a part of his "Lepidoptera Exotica," with three coloured plates of new or unfigured species. In the two parts already issued, which are before us, the figures are admirably done, and very handsome; whilst the descriptive text is concise, and in Latin in part. Some of Mr. Wallace's Bornean butterflies are figured in the second part. E. R. L.

Physiology of the Human Voice.—*Physiologie und Pathologie der Menschlichen Stimme.* By Dr. M. J. Rossbach. (Würzburg. London: Williams & Norgate.)

A TREATISE on the physiology of the voice, intended by the author to be useful not only to physiologists and pathologists, but also to those engaged in singing or in teaching singing. A chapter on the nature and qualities of sounds, based on Helmholtz' well-known work, and a short one on musical instruments, introduce the main topic, the physiology of the human organ of voice. There are also separate chapters on the vocal register, the different kinds of voice, and the relations of voice, speech, and song.

The Convolutions of the Brain.—*Die Hirnwindungen des Menschen.* By Alex. Ecker, Professor of Anatomy in the University of Freiburg. (Brunswick, 1869. London: Williams and Norgate.)

A SUCCINCT but detailed description of the various Convolutions of the Brain, intended chiefly for the use of physicians. It is illustrated by half-a-dozen outline sketches. The references to the development of the convolutions are not very full, but the author promises a more complete account elsewhere.

The Absolute Value of Knowledge.—*Der Sebstandige Werth des Wissens.* By Prof. K. Rokitansky. (London: Williams and Norgate.)

THE Materialist school of philosophy are just now getting very badly treated by men of science, much to the astonishment, it appears, of the general public. Mr. Huxley has startled the world by proclaiming himself in a way a disciple of Berkeley and Kant, and here is Rokitansky, the great master of modern pathological anatomy, walking in a similar path. To many minds pathological anatomy would seem to be intensely materialistic. It is not so, however, to the Viennese professor. This little lecture is chiefly devoted to a development of idealism: of that kind of idealism, moreover, which "makes the objective wholly and in every way dependent on the subjective, for the former is but the projection of the latter."

Tables of Pomona.—*Tafeln der Pomona, mit Berucksichtigung der Storungen durch Jupiter, Saturn, und Mars.* By Dr. Otto Lesser. Publication der Astronomischen Gesellschaft. (Leipzig: Engelmann.)

THESE tables of Pomona are founded on the disturbance of the planets Jupiter, Saturn, and Mars, calculated according to Hansen's method, and published by the author in Nos. 1596-7 of the *Astronomische Nachrichten.* The preface gives a full account of the character of the tables, illustrated in the usual manner by the calculation of the place of the planet Pomona for a given time.

Although it might seem that the construction of a series of tables as full and as elaborate as Bouvard's Tables of Jupiter and Saturn, would be a waste of labour in the case of a minute planet like Pomona, not merely invisible to the naked eye, but not appreciably affecting by its influence any of the great planets of our scheme, yet this is not in reality the case. Though Pomona cannot affect the other planets, yet these affect Pomona. Her sister orb, Themis, has lately been made the means of affording a useful estimate of Jupiter's mass, through the careful consideration of the perturbations which that planet exerts upon the tiny asteroid. Long since Nicolai applied the perturbations of Juno, Encke those of Vesta, Gauss those of Pallas, and Brünnon those of Iris, to the same end. The more such researches are multiplied, the more exact will be our estimate of the mass of the principal planets of the solar system. Therefore, the present tables, by means of which it will be rendered an easy matter to estimate the disturbing action of Jupiter, will have a high value. In a less exact but not unsatisfactory manner, the mass of Mars may be estimated from the same tables, since in certain positions the disturbances of Pomona caused by Mars' attraction can be readily separated from those of Jupiter. R. A. P.

SCIENCE-TEACHING IN SCHOOLS*

THE claims of Physical Science, on *à priori* grounds, to a fair place in the course of school work, have been abundantly vindicated, and are, I suppose, established. But the method and details of its teaching, the books and apparatus which it requires, and the amount of time which must be given to it, are points which can be decided only by experiment, and have not yet been decided at all. I cannot premise too distinctly that the aim of this paper is practical. Of the necessity for teaching science to their boys many good schoolmasters are convinced; as regards the machinery by which it is to be taught, they mostly confess their ignorance, and cry aloud for guidance. In my own school it has been taught systematically for the last five years, and I offer the fruit of this experience, very humbly, to all who are interested in Education.

The subjects to be taught—the time to be spent upon them—the books and apparatus necessary—and the mode of obtaining teachers—are the points on which information seems to be required. I will take them in order.

The subjects which naturally suggest themselves as most essential are Experimental Mechanics, Chemistry, and Physiology. But it has been urged by high authority, familiar to the members of this Association, that between Chemistry and Physiology Systematic Botany should be interposed, as well because of the charm this science lends to daily life, as from its cultivating peculiarly the habit of observation, and illustrating a class of natural objects which are touched indirectly or not at all by the other sciences named. Whether all these four subjects can be taught depends upon the period to which school education is protracted; but at any rate, let these, and none but these, employ the hours assigned especially to Physical Science, in the scheme of actual work in school. Abundant opportunity will remain for less direct instruction in many other branches of science. The Geographical lectures, if properly treated, will include the formation of the earth's crust, with the classification and distribution of its inhabitants, both animal and vegetable, both extinct and recent. The possession of meteorological instruments, whose observations are regularly taken, and their computations worked by the boys, will almost insensibly teach the principles of atmospheric phenomena; while such books as Maury's "Physical Geography of the Sea," Airy's "Popular Astronomy," and Herschel's "Meteorology," may be given as special matter for annual scientific prizes. The laws of light and heat will be taught as prefatory to chemistry. Electricity attracts boys so readily that with very little help they will make great progress in it by themselves. The mathematical master, whose best boys are well advanced, will not be satisfied till he has obtained a transit instrument and a mural circle. And the wise teacher, living in the country, will not disdain to encourage a knowledge of natural history. He will know that it is not only ancillary to severer scientific study, but in itself a priceless and inexhaustible resource. By country walks, by well-chosen holiday tasks, by frequent exhibitions of his microscope, he will not only add to the intellectual stock of his boys, but will build up safeguards to their moral purity. Indeed, even without such encouragement, boys who are trained thoroughly in certain sciences will of their own accord seek to become acquainted with other and collateral ones. Cases multiply in my own experience where pupils of a chemistry class have taken up electricity, pupils of a geography class mineralogy, pupils of a physiology class microscopy, and I need hardly say that boys make nothing their own so thoroughly as that which they select themselves.

The time to be given to science should not be less than three hours a week. At this rate two years may be given to mechanics, two years to chemistry, one year to botany; while the rest, if any remain, will be free for physiology. We need not be afraid of beginning early. A boy of eleven years old, fresh from an intelligent home, where his love of observation has been fostered, and his inquiries have been carefully answered, is far more fit to appreciate natural laws than a much older boy, round whose intellect, at an old-fashioned school, the shades of the prison house have steadily begun to close. Most schools are now divided into lower, middle, and upper. I would commence the study of mechanics with the junior class in the middle

* A Paper read before the British Association at Exeter, by the Rev. W. Tuckwell. Communicated by the Author.

school. For the first year the teaching may be *viva voce*, with easy problems and abundant experiment; care being taken that each week's lectures shall be reproduced on paper, and great attention being paid to correct drawing. In the second year the teaching will be more minute and more extended, and a good book will be mastered. At the end of this time the class is fit to pass creditably the Oxford Local Examination for juniors, and has done with mechanics for the present. The third and fourth years will be given to inorganic chemistry. The third year will include only lectures in the class room; a text-book being used, experiments being shown by the master, but no laboratory work being done by the boys. The fourth year's work will be conducted entirely in the laboratory, each boy manipulating with his own instruments at his own table. At the expiration of these two years the class will be qualified for the chemistry examination in the London University Matriculation. The fifth year is given to botany. If a good book is used, if each boy works for himself with lens and knife, if Henslow's Schedules, or a modification of them, are regularly filled up; above all, if plates are not made to do the work of living plants, the pupils will at the year's end thoroughly understand the principles of classification, will know the characteristics of at least all the British orders, and will be able with the help of Bentham or Babington to make out almost any English flower. The boys who have completed this course will be from 16 to 17 years old. Some of them will now be leaving school; those who remain will give the rest of their time to physiology. They will begin with human and will pass to comparative physiology, using in the first Professor Huxley's valuable little book; dependent for the second, of which no school manual exists, on the skill and method of their teacher. But whether at the earlier or the later age, they will pass out into the world immeasurably superior to their contemporaries who know not science, with doors of knowledge opened which can never again be closed; with a fund of resource established which can never be exhausted; with minds in which are cultivated, as nothing else can cultivate them, the priceless habits of observation, of reasoning on external phenomena, of classification, arrangement, method, judgment.

The subject of books and apparatus, involving as it does the question of expense, is of the highest practical importance. Apparatus need not cost much; but it may, and if possible it should, cost a great deal. While poor and struggling schools may begin cheaply and proceed gradually, institutions which can spend money on racket courts and gymnasiums ought not to grudge it on museums and botanic gardens. We have taught mechanics efficiently, that is to say, we have passed our classes for the last three years in the Oxford Local, with a good air-pump, a set of pulleys, models of the force-pump and the common pump, with Keith Johnston's scientific maps, and with the diligent use during the second year of Newth's "Natural Philosophy." But we have lost no opportunity of making the boys acquainted with machinery; from the crane and the water-mill of our daily walks, to the steam engine and the spinning jenny of the manufactory; for he who has not examined engines at work will never understand them clearly, or describe them correctly. For teaching chemistry, a laboratory is absolutely essential. No matter how rough or shabby a room, so that it be well ventilated, have gas and water laid on, and will hold from sixteen to twenty boys. I hold in my hand the model of a cheap laboratory table, on the scale of two inches to a foot. It is about nine feet by three, and contains eight compartments, each two feet by sixteen inches, with two slight shelves, and a special recess for the teacher. It costs about 4*l.* If made for twice the number of boys, it may be made at about nine shillings per boy. The general laboratory stock, including a still, a stove or furnace, gas jars, a pneumatic trough, a proper stock of retorts, crucibles, tubing, &c., and the necessary chemicals will cost under 12*l.* Each pair of pupils must have also between them a set of test tubes, a washbottle, a spirit lamp, a waste basin beneath their table, and twenty-four bottles of test solutions, while each boy has his own blowpipe, tripod and stand, pestle and mortar, and three beakers. These will cost each boy about eight shillings. He will replace everything that he breaks, and will receive the value of his stock from his successor when he quits the class. The text-book used should be Roscoe's, or Williamson's, and a large black board is quite indispensable. In botany the book for the boys' use is Professor Oliver's Lessons; but the teacher will find great advantage from Le Maout's "Leçons de Botanie." An excellent modification of Henslow's Schedule is published by Professor Babington for the use of his Cambridge classes, and Lindley's "Descriptive Botany," price one shilling, is a most useful help. Every boy should be furnished with a small deal board, a lens, and a sharp knife. The botanical microscope which I exhibit, including a lens fixed or movable, a black glass stage, two dissecting needles and a forceps, is made by Mr. Highley, of Green-street, Leicester-square. If they are ordered by the dozen he will furnish them at six shillings each. Flower trays, such as I hold in my hand, should be kept constantly in use; the boys being encouraged to bring in wild flowers, and to place them in their appropriate niches. Their cost per tray, holding eighteen bottles, is under two shillings. Fitch's diagrams designed for the Committee of Council on Education, which cost 2*l.* 9*s.* the set, are a valuable help to the lectures; and for schools which have large purses or liberal friends, Dr. Auzoux's Models of Plants and Plant Organs, ranging in price from 20 to 100 francs, and ten times the size of life, form a luxuriant assistance to beginners, which only those can appreciate who have worn out their eyesight and their temper over a composite floret or the glume of a small grass. The same excellent modellist, whose catalogue is on the table, provides every organ necessary for the study of comparative and human physiology; and his prices ought not to be beyond the reach of any prosperous school. In any case a skeleton will be necessary, and will cost about £5; and if the Committee of Council were to authorise the reproduction of such typical physiological cases as, from the skilful hands of Mr. Charles Robertson of the Oxford Museum, drew so many admirers in the Exhibition of 1862, these would find immediate purchasers in many of our schools. At present teachers want the skill or the leisure to make their own preparations, and they cannot buy them. A good set of meteorological instruments costs from £16 to £20, but these, with astronomical apparatus, are a costly luxury, and may be left out of the list of indispensable necessities. I cannot think that any school, professing to teach science systematically, will be long satisfied without a typical museum. As scientific work proceeds, specimens of all kinds, some purchased for lecture work, others given by friends or collected by the boys, will gather and increase, till the class-room cupboards and shelves are choked, and a special room must be devoted to them. Here will be arranged, in one place rocks and fossils, in another trays of minerals, in a third zoological specimens, in a fourth physiological preparations. The driest corner in the room will be assigned to the Herbarium, a small library of scientific reference will give promise of the future. Everything not typical will be rigorously excluded; every case will be so carefully arranged and so plainly labelled as to tell the history of its contents to the eye of the least instructed observer. And it will be hard if some corner of the playground cannot be laid out as a botanic garden. In the crowded school premises which we are happily leaving I have found room for nearly four hundred plants, and at the new school to which we are about to migrate, I shall riot in two acres of garden ground, with a pond for water plants and a sheltered rockery for ferns.

It remains only to examine the mode of obtaining teaching power; a point which presses heavily on many head-masters who have themselves no knowledge of science. That all head-masters should have such knowledge is a fact which, if science is to be taught at all, trustees and governing bodies must come to recognise before long: meanwhile every school which teaches science thoroughly is training skilled teachers for a not distant generation. Institutions which can give so high a salary as to command a London bachelor of science or a first class Oxford or Cambridge man, will find no more difficulty than attends the choice of all masters: where this is not the case it is sometimes possible by combining mathematics with physical science to tempt a superior man with a sufficient income; and, if only a small salary can be given, the ordinary pass B.A. of the London University will sometimes make a fairly good teacher. But one point has struck me forcibly in my own experience; namely, the unexpected value of general culture in teaching special subjects. The man who knows science admirably, but knows nothing else, prepares boys well for an examination; but his teaching does not stick. The man of wide culture and refinement brings fewer pupils up to a given mark within a given time: but what he has taught remains with them; they never forget or fall back. I am not sure that I understand the phenomenon, but I have noted it repeatedly.

I cannot end this paper without a word as to the educational results which our five years' experience has revealed. The system has brought about this result first of all, that there are no dunces in the school. In a purely classical school, for every promising scholar there are probably two who make indifferent progress, and one who makes no progress at all; and a certain proportion of the school, habitually disheartened, loses the greatest boon which school can give, namely, the habit and the desire of intellectual improvement. By giving importance to abstract and physical science, we at once redress the balance. Every boy progresses in his own subject; some progress in all; no one is depressed, no one thinks learning hateful. Secondly, the teaching of science makes school-work pleasant. The boy's evident enjoyment of the scientific lesson rouses the emulation of other masters. They discover that the teaching of languages may become as interesting as the teaching of science. They realise—a point not often realised—the maxim of Socrates, that no real instruction can be bestowed on learners "*παρὰ τοῦ μὴ ἀρέσκοντος*, by a teacher who does not give them pleasure." Lastly, the effect on the boy's character is beyond all dispute. It kindles some minds which nothing else could reach at all. It awakes in all minds faculties which would otherwise have continued dormant. It changes, to an extent which we cannot over-estimate, the whole force and character of school-life both to the learner and the teacher. It establishes, as matter of experience, what has long been urged in theory, that the widest culture is the noblest culture; that universality and thoroughness may go together; that the system which confines itself to a single branch of knowledge, does not gain, but loses incomparably, by its exclusiveness: that observation, imagination, and reasoning may all be trained alike; that we may, and so we must, teach many things, and teach them well.

W. TUCKWELL

THE LATE PROFESSOR GRAHAM

AT 9 o'clock in the evening of Thursday, the 16th September, 1869, died at his house, No. 4, Gordon Square, a man whose name will be honoured as long as true greatness is appreciated.

Thomas Graham spent his life in reading the book of Nature, and giving to mankind a knowledge of the truths which he found there. His greatness is to be measured not merely by the amount and importance of the knowledge which he thus gave, but even more by the singleness and strength of purpose with which he devoted his whole life to labours of experimental philosophy.

Some men have made important discoveries by occasionally applying to experimental investigation, powers of mind which they exerted usually in the pursuit of their own worldly advancement.

But from an early age Graham's one great object of life was the discovery of new truths, and he appreciated so fully the value of such work that he resolved to make any personal sacrifices which might be needed for its sake. And nobly he kept his resolution; for at an early stage of his career he endured, for the sake of pursuing chemistry, privations and sufferings so severe, that they are believed to have permanently injured his constitution; and at its very end, long after he had attained a world-wide reputation, when his delicate frame sorely needed the repose which was at his command, he continued to labour even more effectively than before, and to enrich science with new discoveries.

It might be difficult to find in history a character so perfect in its noble simplicity and elevation.

Graham was born at Glasgow, on the 21st December, 1805, the eldest of a family of seven, of whom only one survives.

He went to the English preparatory school at Glasgow, in 1811, and was there under the care of Dr. Angus. In the year 1814 he was removed to the High School, where for four years his studies (which included the Latin language) were directed by Dr. Dymock, and subsequently for one year by the Rector, Dr. Chrystal, under whom he studied Greek. It is said that during these five years he was not once absent at school-time. In 1819 he commenced attendance in the University classes in Glasgow.

Thomas Thomson then occupied the Chair of Chemistry, and young Graham benefited by his instruction, as also by that of Dr. Meikleham, the Professor of Natural Philosophy.

By this time he had already acquired a strong taste for experimental science, and formed a wish to devote himself to chemistry. His father, an able and successful manufacturer, had formed different views for his future career, and wished him to become a minister of the Scotch Church. It is hardly to be wondered at that the father should not have seen in the prosecution of science much scope for an honourable or advantageous career; but young Graham had already seen something of the means afforded by experimental science of getting knowledge from the fountain head—from Nature herself. He felt the need of more such knowledge to mankind, and his scheme of life was formed accordingly.

After taking the degree of M.A. at Glasgow, he continued his studies for two years at Edinburgh, and there studied under Dr. Hope, and enjoyed the friendship of Prof. Leslie. On his return to Glasgow, he taught mathematics for some time at the suggestion and under the patronage of Dr. Meikleham, and subsequently opened a laboratory in Portland Street, Glasgow, where he taught chemistry. It is probable that some of the severest trials of his life occurred at about this period.

While absent from Glasgow he was in the habit of writing regularly and at great length to his mother, and from the tenor of these letters it is easy to see what that mother must have been to him. A writer on the social position of women has described the feelings of boys towards their mothers as scarcely amounting to respect! Young Graham's mother seems to have been his guardian angel, sympathising with his hopes and his sorrows; and certainly his feelings towards her would have been very inadequately described by that frigid word. While studying at Edinburgh he earned, for the first time in his life, some money by literary work, and the whole sum (6*l.*) was expended in presents to his mother and sisters.

In 1829 he was appointed lecturer on Chemistry at the Mechanics' Institution, Glasgow, in place of Dr. Clark; but the decisive step of his life was in the subsequent year. It was in 1830 that he was appointed Professor of Chemistry at the Andersonian University, Glasgow; and it is said that his mother, who was on her deathbed, lived to hear the glad tidings of his appointment. He was now more favourably circumstanced for experimental labours, and we find that the seven years spent at the Andersonian University were years of great activity.

In 1837 he was appointed Professor of Chemistry in the London University, now called University College, London, and he occupied that chair with great distinction till the year 1855, when he succeeded Sir John Herschel as Master of the Mint, which appointment may be considered an acknowledgment on the part of the Government of his scientific services and of his high character.

His numerous discoveries have been much quoted. Some of their theoretical bearings claim a brief notice here.

His investigation of the phosphates is remarkable in many ways. It was known that solutions of phosphoric acid in water vary in their properties; and chemists were satisfied with giving a name to the changes without investigating their nature. These solutions contained phosphoric acid and water, and were assumed to have like composition. They were accordingly called isomeric. Graham observed that they differ from one another in the proportion of water combined with the acid, and constitute in reality different compounds.

He knew that water combines with acids as other bases do, and he showed that the various compounds of phosphoric acid and water constitute distinct salts, each of which admits of its hydrogen being replaced by other metals without disturbance of what we should now call the type. Thus, to use our present notation, the three hydrates PO_4H_3, $P_2O_7H_4$, PO_3H, correspond to the following proportions of acid and water:—

$$P_2O_5 + 3H_2O = 2PO_4H_3$$
$$P_2O_5 + 2H_2O = P_2O_7H_4$$
$$P_2O_5 + H_2O = 2PO_3H$$

THOMAS GRAHAM (from a recent Photograph)

Graham observed that the hydrate PO_4H_3 is constituted like a salt, inasmuch as its hydrogen can be replaced atom for atom by other metals, like sodium, potassium, &c., forming such compounds as PO_4NaH_2, PO_4Na_2H, &c.

In order to appreciate duly the powers of mind of the author of this admirable research, we ought to compare his methods of reasoning with those generally prevalent among contemporary chemists, and on the other hand with the methods of to-day. One would fancy that Graham had been acquainted with the modern doctrines of types and of polybasic acids, so clearly does he describe the chemical changes in matter-of-fact language, and so consistently does he classify the compounds by their analogies. At that early period we find Graham considering hydrogen, in various salts, as a basylous metal; an idea which (in spite of its undeniable truth) some chemists of the present day have not fully realised.

Amongst minor chemical researches may be mentioned a series of experiments on the slow oxidation of phosphorus by atmospheric air. He discovered that this process (and the faint light which accompanies it) is arrested by the presence in the air of a trace of olefiant gas, $\frac{1}{150}$ of the volume of the air being sufficient for the purpose. Still smaller proportions of some other vapours were found capable of producing this same effect; spirits of turpentine being particularly remarkable, as less than a quarter of a thousandth of its vapour with air was found sufficient to prevent the slow oxidation of phosphorus.

On another occasion Graham investigated phosphuretted hydrogen, and made some remarkable observations concerning the conditions of the formation of the spontaneously inflammable gas. One of these deserves especial notice in connection with the action of olefiant gas, and in preventing the oxidation of phosphorus. He found that phosphuretted hydrogen is rendered spontaneously inflammable by the admixture of a very small proportion of an oxide of nitrogen, probably nitrous acid.

One of the most obscure classes of combinations are those which water forms with various salts. These bodies are characterised by the chief peculiarities which belong to definite chemical compounds; but chemists are as yet unable to explain them.

Water so combined is called water of crystallisation, and is said to be physically, not chemically, combined. A very convenient way of getting rid of a difficulty, by passing it on to our neighbours.

Graham examined the proportion of such water of crystallisation in a considerable number of salts, and he moreover examined the properties which it has when so combined. He found that some of the water in an important class of sulphates is held far more firmly than the remainder, and with force equal to that with which water is held in various chemical compounds. He showed that such firmly combined water can be replaced by salts in a definite chemical proportion. In fact, he got fairly hold of the subject by chemical methods, and laid the foundation for an explanation of it.

He discovered and examined compounds of alcohol with salts, and derived from them valuable evidence of the analogy between alcohol and water.

On a later occasion he made a series of important experiments upon the transformation of alcohol into ether and water, by the action of hydric sulphate. Liebig had endeavoured to explain the formation of ether in this process, by representing it as due to the decomposition at a high temperature of a compound of ether previously formed at a lower temperature; such decomposition being due to the increased tension of the vapour of ether at the higher temperature.

Graham justly argued that if the decomposition were due to the tension of ether vapour, it would not take place, and ether would not be formed, if the tension were not allowed to exert itself. He heated the materials in a closed tube, and proved that ether was formed, although the tension of its vapour was counteracted by the pressure thus obtained.

The line of research which occupied most of his attention, and in which his results were perhaps the most important, was that of diffusion; and it would be difficult to over-estimate the importance to molecular chemistry of his measurements, of the relative velocities of these spontaneous motions of particles of matter, whether in the state of gas or in the liquid state.

It was known that 1 part by weight of hydrogen occupies the same volume as 16 parts by weight of oxygen when measured at like temperature, and under like pressure. Chemical investigations prove that these equal volumes of the two gases contain the same number of atoms. We also know that the atoms in such a gas are in rapid motion, and resist the pressure to which the gas is at any particular time exposed, by striking against the surface which presses them together with force equal to that which presses them together.

Thus a given volume of hydrogen is maintained against the atmospheric pressure by an energy of atomic motion, equal to that of the same volume of oxygen. Each atom of hydrogen accordingly exerts a mechanical energy equal to that of each atom of oxygen; but we have seen that the hydrogen atom is much lighter than the oxygen atom, and accordingly it must move with much greater velocity than the oxygen atom.

Now Graham allowed hydrogen to escape through a very small hole in a plate of platinum; and allowed oxygen to escape under similar circumstances. He found that each hydrogen atom moves out four times as fast as each oxygen atom. His experiments were so arranged as to enable him to measure the relative velocities of certain motions of the atoms—motions not imparted to them by any peculiar or unnatural conditions, but belonging to them of necessity in their natural state. He found, moreover, that heat increases the velocity of these atomic motions, whilst increasing the force with which a given weight of the gas resists the atmospheric pressure.

The study of the condensation of gases by solids, and the combination of soluble compounds with membranes led him to discoveries which are likely to be of great value to physiologists in explaining processes of absorption and secretion.

Thus he found that oxygen is absorbed to a greater extent than nitrogen by caoutchouc, and that when a bag made of a thin membrane of this substance is exhausted by means of a good air-pump, the oxygen and nitrogen diffuse through it (probably as condensed liquids), and evaporate inside the bag in different proportions from those in which they are present in air; the oxygen rising to over 40 per cent. of the diffused air. Again, a mixture of hydrogen and oxygen was separated almost completely by the action of palladium, which condensed the hydrogen in very large quantity, and the oxygen very slightly.

Perhaps the most remarkable substances discovered in the course of his experiments on diffusion, were the soluble modifications of tungstic and molybdic acids, ferric oxide, &c., and the process by which these bodies were obtained was, perhaps, the most instructive part of the result; proving, as it does, that in their salts, these bodies have properties different from those which they normally possess in the free state; and retain them when the other constituent is removed by a sufficiently gentle process.

Another remarkable fact which bears on a most important theory, is the separation effected by Graham of potassic hydrate and hydric sulphate, by diffusion of potassic sulphate in aqueous solution—a fact which requires us to admit that the solution of the salt in water contains those products mixed with one another; just as much as the experiment of diffusing air through a porous clay pipe, and getting its constituent in a different proportion from that of the original air, proved that air is a mixture and not a compound of the two gases.

In his later researches, Graham was assisted by Mr. W. C. Roberts, and cordially acknowledged the zeal and efficiency displayed by that able young chemist. Graham's scientific influence extended beyond his researches; for, on the one hand, his lectures for 18 years at University College were remarkable for logical accuracy and clearness of exposition, and were highly valued by those who had the privilege of hearing them. On the other hand, his "Elements of Chemistry" is a masterly exposition of the best known facts of the science and of chemical physics. It was translated into German, and afforded at that time the most philosophical account of the working and theory of the galvanic battery.

In many of his ideas Graham was in advance of his contemporaries, and it might be difficult to find a chemist who has dealt more cautiously with general questions and delicate experimental operations,—or one whose results, in each direction in which he has worked, may more safely be expected to stand the test of future investigations.

A. W. WILLIAMSON

THE MEETING OF GERMAN NATURALISTS AND PHYSICIANS AT INNSBRUCK, TYROL

FROM the 18th to the 24th of September last the little town of Innsbruck wore an air of unwonted bustle and excitement. Its population, already augmented by the usual throng of summer tourists, was swelled by the advent of somewhere about 800 additional visitors—professors, doctors, directors, men of all sciences, often with their wives and daughters, who had come from all parts of Germany to attend the forty-third Meeting of the German Naturalists and Physicians. These meetings resemble those of our own British Association, though they differ in several very characteristic respects. One of the first contrasts to strike an Englishman is the entire absence of private hospitality. Everybody, so far as we can learn, is in private lodgings or in a hotel; and there are no such things as dinner-parties. Although our own customs in these respects are certainly very pleasant, there can be no doubt that the German fashion leaves the visitors more freedom, and allows them much more opportunity of seeing and talking with the friends they most wish to meet. With us it is no easy matter to get together a party of chemists, or geologists, or physiologists, to hold a social gathering after the labours of the sections are over. We are all either staying with friends, or invited to dinner, or engaged in some way. But at the German meetings such social reunions are one of the distinguishing features. One o'clock in the day brings with it the necessity for dining, and numerous dinner parties are improvised there and then; friends of like tastes, who have not met perhaps for a year before, adjourn to a *restauration* or *kaffee-haus*, and while eating the meal have a pleasant opportunity of comparing notes, and discussing questions which have in the interval arisen.

Another feature of contrast is in the length of time devoted to the sitting of the sections. At the British Association the sections open their sittings at eleven in the forenoon; and the work goes on steadily all day without intermission till four or five o'clock in the afternoon. But, in Germany, the sittings commence sometimes as early as 8 A.M., and are frequently over by ten or eleven o'clock, leaving the rest of the day for some short after-dinner excursion, or for general miscellaneous intercourse among the members. In fact, the German meetings are designed less for the purpose of bringing forward new scientific work, than with the view of affording to men of science opportunities of becoming personally acquainted with each other, and of discussing the value and bearing of recent contributions to knowledge. Hence, the papers which are brought before the sections, contain, to a large extent, outlines, summaries or notices of recent researches, and exhibitions of books, maps, memoirs, specimens, experiments, &c., which have recently attracted notice.

In our British Association gatherings, there is probably more hard work than in those of our German brethren, and I daresay there is as much opportunity for sociality as suits our national temperament. For our Association is meant, not merely to promote a friendly intercourse among scientific men, but to be a kind of propagandist for the advancement of science through the general community. So we make a compromise between sober, serious, hard work for science on the one hand, and unrestrained festivities on the other. The German meetings keep less prominently before them the scientific culture of the world outside, and aim rather at the strengthening of the hands of the individual worker.

From the papers read at the different sections; from the discussion which they elicited; and still more perhaps from the public addresses on subjects of general interest given to the whole assembled meeting; one could gather some suggestive traits of the present current of thought in at least one great section of the cultivated society of Germany. What specially struck me was the universal sway which the writings of Darwin now exercise over the German mind. You see it on every side, in private conversation, in printed papers, in all the many sections into which such a meeting as that at Innsbruck divides. Darwin's name is often mentioned, and always with the profoundest veneration. But even where no allusion is specially made to him, nay, even more markedly, where such allusion is absent, we see how thoroughly his doctrines have permeated the scientific mind even in those departments of knowledge, which might seem at first sight to be furthest from natural history. "You are still discussing in England," said a German friend to me, "whether or not the theory of Darwin can be true. We have got a long way beyond that here. His theory is now our common starting point." And so, as far as my experience went, I found it.

But it is not merely in scientific circles that the influence of Darwin is felt and acknowledged. I do not think it is generally known in England, that three years ago, when, after the disastrous war with Prussia, the Austrian Parliament had assembled to deliberate on the reconsolidation of the empire, a distinguished member of the Upper Chamber, Professor Rokitansky, began a great speech, with this sentence:—"The question we have first to consider is, Is Charles Darwin right or no?" Such a query would no doubt raise a smile in our eminently unspeculative houses of legislature. But surely never was higher compliment paid to a naturalist. A great empire lay in its direst hour of distress, and the form and method of its reconstruction was proposed to be decided by the truth or error of the theory of Darwin. "The two men," said one able physician of Vienna to me (himself, by the way, a North-German), "who have most materially influenced German thought in this country are two Englishmen—George Combe and Charles Darwin."

There was another aspect of the tone of thought at Innsbruck, which could not but powerfully impress a Briton. Although we were assembled in the most ultra-Catholic province of Catholic Austria, there was the most unbridled freedom of expression on every subject.

In an address on recent scientific progress, Helmholtz thus expressed himself—"After centuries of stagnation physiology and medicine have entered upon a blooming development, and we may be proud that Germany has been especially the theatre of this progress—a distinction for which she is indebted to the fact that among us, more than elsewhere, there has prevailed a fearlessness as to the consequences of the wholly known Truth. There are also distinguished investigators in England and in France, who share in the full energy of the development of the sciences, but they must bow before the prejudices of society, and of the Church, and if they speak out openly, can do so only to the injury of their social influence. Germany has advanced more boldly. She has held the belief, which has never yet been belied, that the full Truth carried with it the cure for any injury or loss which may here and there result from partial knowledge. For this superiority she stands indebted to the stern and disinterested enthusiasm which, regardless alike of external advantages and of the opinions of society, has guided and animated her scientific men."

This liberty of expression, however, seemed sometimes apt to wear not a little the aspect of a mere wanton defiance of the popular creed. Yet it was always received with applause.

In an address on the recent progress of anthropology, Karl Vogt gave utterance to what in our country would be deemed profanity, such as no man, not even the most free-thinking, would venture publicly to express. Yet it was received, first with a burst of astonishment at its novelty and audacity, and then with cries of approval and much cheering. I listened for some voice of dissent, but could hear none. When the address, which was certainly very eloquent, came to an end, there arose such a prolonged thunder of applause as one never hears save after some favourite singer has just sung some well-known air. It was a true and hearty *encore*. Again and again the bravos were renewed, and not until some little time had elapsed could the next business of the meeting be taken up. Not far from where I was standing, sat a Franciscan monk, his tonsured head and pendent cowl being conspicuous among the black garments of the *savans*. He had come, I daresay, out of curiosity to hear what the naturalists had to say on a question that interested him. The language he heard could not but shock him, and the vociferation with which it was received must have furnished material for talk and reflection in the monastery.

ARCH. GEIKIE

TRIASSIC DINOSAURIA

It will probably interest geologists and palæontologists to know that a recent examination of the numerous remains of *Thecodontosauria* in the Bristol Museum, enables me to demonstrate that these Triassic reptiles belong to the order *Dinosauria*, and are closely allied to *Megalosaurus*. The vertebræ, humerus, and ilium, found in the Warwickshire Trias, which have been ascribed to *Labyrinthodon*, also belong to *Dinosauria*. The two skeletons obtained in the German Trias near Stuttgart, and described by Prof. Plieninger, some years ago, are also unquestionable *Dinosauria;* and, as Von Meyer is of opinion, probably belong to the genus *Teratosaurus*, from the same beds. Von Meyer's *Platæosaurus*, from the German Trias, is, plainly, as he has indicated it to be, a Dinosaurian.

As Prof. Cope has suggested, it is very probable that *Bathygnathus*, from the Triassic beds of Prince Edward's Island, is a Dinosaurian; and I have no hesitation in expressing the belief, that the *Deuterosaurus*, from the Ural, which occurs in beds which are called Permian, but which appear to be Triassic, is also a Dinosaurian. It is also very probable that *Rhopalodon*, which occurs in these rocks, belongs to the same order. If so, the close resemblance of the South African *Galesaurus* to *Rhopalodon*, would lead me to expect the former to prove a Dinosaur.

I have found an indubitable fragment of a Dinosaurian among some fossils, not long ago sent to me, from the reptiliferous beds of Central India, by Dr. Oldham, the Director of the Indian Geological Survey. Further, the determination of the Thecodonts as *Dinosauria*, leaves hardly any doubt that the little *Ankistrodon* from these Indian rocks, long since described by me, belongs to the same group.

But another discovery in the same batch of fossils from India, leaves no question on my mind that the Fauna of the beds which yield Labyrinthodonts and Dicynodonts in that country, represents the terrestrial Fauna of the Trias of Europe. I find, in fact, numerous fragments of a crocodilian reptile, so closely allied to the *Belodon* of the German Trias, that the determination of the points of difference requires close attention, associated with a *Hyperodapedon*, larger than those discovered in the Elgin Sandstones, but otherwise very similar to it.

Thus, during the Triassic epoch, extensive dry land seems to have existed in North America, Western and Central Europe, Eastern Europe, Central India, and South Africa, as it does now; and, throughout this vast area, the *Dinosauria*—the links between reptiles and birds—seem to have been represented by not fewer, probably by many more, than nine or ten distinct genera.

I hope, shortly, to have the honour of placing the details of the researches into the structure and distribution of the *Dinosauria*, in which I have been engaged for the last two years, and of which the above notice is one of the results, before the Geological Society.

T. H. HUXLEY

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents.*]

The Suez Canal

THE all-engrossing topic of the day is the Suez Canal, about which some diversities of opinion still exist. As for many years back I have had my attention particularly drawn to some of the chief matters in dispute, having been engaged on the largest irrigation works in India, I venture to trouble you with the following remarks.

Engineering science and indomitable energy have, in the case of the Suez Canal, overcome difficulties which at one time were considered insurmountable; but even up to the present moment doubts still exist, and some fear that the whole scheme may yet prove a failure, owing to the débris of the Nile travelling eastward transported by the currents of air and water. That we can overcome the former is, in my opinion, beyond all doubt; for it is found that whenever an irrigation channel is run out from the Jumna Canal into the great desert of Northern India, rich vegetation takes the place of arid sand. And so in Egypt will irrigation force back the desert; so the only question is, Can irrigation be carried out on an extensive scale? And of this also I have no doubt, for the enormous volume of water which now flows into the sea and is lost, is quite sufficient to reclaim the whole of the desert.

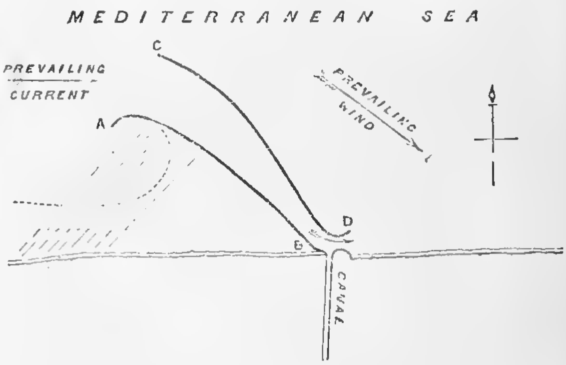
It may be asked, Can the water be made to flow over the desert? And of this I hold that there can also be no doubt. The very name of the Timsa Lake proves, I think, that the Nile, or at least a branch of it, flowed eastward, for the word *Timsa* signifies crocodile, showing that the water must at one time have been brackish or fresh, for these creatures could not have existed in this lake had it been salt as at present. If, therefore, a portion of the Nile water at one time flowed eastward, there can be no great engineering difficulty to make it do so again; and I am almost inclined to think that it would have been better to have made the canal a fresh-water one, for it is only by vegetation, the produce of irrigation, that the desert can be kept under control. Other advantages may be cited, such as cleaning the bottom of ships by bringing them into fresh water, and the prevention of any of the disturbed and very muddy waters along the Mediterranean coast getting admission into the canal; for by keeping the water in the canal at a higher level than that of the sea at both ends there could only be an outflow. So all the water wasted would be expended on lockage.

It may be objected that the fresh-water canal would get silted up by the muddy waters of the Nile; but could not this Timsa Lake be used as a silt-trap? I do not mean to say, that the present canal will be a failure because it has not been made a fresh-water one; but what I do think is, that possibly in the end a fresh-water canal would have been best and perhaps cheapest, as the dredging of the canal might have been much reduced,* as the water could have been kept at a higher level in the canal.

The great difficulty, however, to contend against, appears to me to be to keep a deep-water channel at the Mediterranean end of the Canal; and what drew my attention to this more than a dozen years ago, was the fact that the harbour of Alexandria does not get silted up. Some have supposed that the subsidence of the delta accounts for this, and that the small advance of the land on the sea in this direction is owing to a constant sinking of the land. In my opinion a very different cause can be assigned: Nature here is working by a very different agency, namely, the current in the Mediterranean which flows eastward all along the African coast, and transports the débris of the Nile, depositing it all along the western portion of the Mediterranean. The fact of the Timsa Lake being at one time fresh or brackish, goes to support this view; so the only question is, Will the cost of continuous dredging be so excessive that the Canal will become a financial failure? On this point I cannot venture to give an opinion, as I have no data, but I think this difficulty may be met by forcing this easterly current to aid in keeping the mouth of the Canal clear of silt deposits.

What aids this current to transport the earthy matter is the beat of the sea always stirring the mud and sand up on the coast, and enabling the water to hold a large proportion of matter in suspension, and even to transport heavy matter.*

The proportion of earthy matter a short distance out to sea is comparatively little, so the great object appears to me to prevent the agitated water travelling as it does at present, and this can be done by arranging the breakwaters somewhat as shown in this diagram.



The breakwater AB is intended to prevent the very muddy water travelling along the coast, and the point A should extend well out into deep water. The breakwater CD is to direct the comparatively pure water where the sea is deep to pass across the mouth of the canal; and by the funnel-mouthed shape thus given, the velocity at D will be increased, and thus keep deep water at the head of the canal. Some may say that the expense will be enormous, and that it will have to be year after year extended. But, in reply to this, I say that deltas do not extend out into the sea at so rapid a rate as some suppose; and that the formation of a delta takes several thousands of years to accomplish, so that in this very delta, the advance is hardly perceptible; and that a sinking of the land has been brought forward, to account for the very slow progress made; while, in fact, Nature has at present a power at work which is quite sufficient to explain the reason why so little advance is made on the sea during the historic period (see my paper on the Delta of the Irrawaddy, read before the Royal Society of Edinburgh in 1857).

In conclusion, I have no doubt this Suez Canal will have many ready to abuse it and say it is a total failure, as has been said of the Ganges Canal; but like the latter work, which last year saved some three million human beings from starvation, so will this canal, I have little doubt, outlive the abuse, and become one of the greatest blessings to the civilised world.

T. LOGIN, C.E., late of the Ganges Canal.

London, Oct. 29, 1869.

* I observe that, in a discussion at the Civil Engineers Institution, the total excavation of the Suez Canal is stated to be 70,000,000 cubic metres. The excavation of the Ganges Canal was 2,547,000,000 cubic feet, or a little over 70,000,000 metres; but this latter does not include some 3,000 miles of distribution channels.

* At Felixstowe, last March, during a gale of wind, I watched a mass of brickwork, some eighteen inches square and about six inches thick, moved along the coast by the action of the waves, which were in an oblique direction to the coast, and no doubt the same takes place along the mouths of the Nile. By a sample I took of this agitated water, I found it contained 0·7375 per cent. of its weight of small pebbles, sand, and mud. This sample was taken at a height of nearly ten feet above the sea, and was got by catching the spray of the sea as it was falling.

NOTES.

BY offering Dr. Temple the Bishopric of Exeter, Mr. Gladstone has removed from his post the most eminent schoolmaster in England. Dr. Temple has done much for the education, present and future, of all classes; and although this is not the place to comment on all he has done in this direction, we may note here what he has done for education in Science. He may fairly claim to be the first head-master who has recognised its importance, and effectively introduced it into his school. And its introduction at Rugby is of special importance, because it is the acknowledged leader in educational progress, and because so many head-masters have been trained there. Now Harrow and Eton, and several other schools are doing something, though none yet with quite the same liberality as Rugby: but it will be instructive to look back ten years, and thus to estimate the advance. Rugby was then the only public school where science was taught at all. But even there it was under great disadvantages. No school was assigned to it; it was an extra, and heavily weighted by extra payment. There was no laboratory, scarcely any apparatus, and scarcely any funds for procuring it. About forty to fifty boys attended lectures on it, but there was no possibility of making those lectures consecutive, and of dealing with advanced pupils. Now there is a suite of rooms devoted to science. A large and excellent laboratory, where thirty boys are working at the same time at practical chemistry with the assistance of a laboratory superintendent, opens into a smaller private laboratory, which is for the use of the master and a few advanced students. This again opens into a chemical lecture room, in which from forty to fifty can conveniently sit. The seats are raised, and the lecture table fitted with all that is required. Adjoining is the physical science lecture room, in which sixty can sit, and of which a part is assigned to work tables. And out of this the master's private room is reached, in which apparatus is kept, and experiments and work prepared. There is a considerable geological museum, and an incipient botanical collection. A Natural History Society meets frequently, and publishes reports and papers contributed by the boys. Five masters take part in teaching natural science. It is introduced into the regular school work (about 360 out of 500 appear to be in the Natural Science classes); being compulsory on all the middle school; an alternative in the upper school; and optional in the Sixth Form. And the result of the teaching has been satisfactory. It has not damaged classics. It has been the means of educating many boys, and has been a visible gain to the great majority; and it has steadily contributed to the lists of honours gained at the University. If Dr. Temple had done nothing else, his name would deserve honour at our hand for having brought about this change. Let us hope that his successor will be equally liberal to science, and maintain its efficiency.

THE public anxiety about the fate of our great explorer, Dr. Livingstone, has been anything but allayed by the recent telegrams from Bombay and Zanzibar, wanting, as they seem to do at present, the stamp of the approval of Sir R. Murchison. The Bombay mail is now hourly expected; and, by the opening meeting of the Royal Geographical Society, Sir Roderick will be in possession of all the data on which to form a complete estimate of the recent intelligence, and will then communicate the results. In the meantime, we wait and hope; Livingstone is not the man to do his work hastily or incompletely, or to return leaving anything unexplored.

THE President of the Royal Society, Sir Edward Sabine, being unable, through pressure of official duty, to accept the Khédive's invitation to be present at the opening of the Suez Canal, was allowed to nominate a gentleman to represent the Royal Society on the memorable occasion. The President's choice, which has been approved by the Council, fell on Mr. J. F. Bateman, C.E. This selection will perhaps gratify the civil engineers as well as the Royal Society, for Mr. Bateman, who is now on his way to Egypt, has made himself known on the Mediterranean, by his land-reclamations in Majorca and at the mouth of the Ebro.

DRS. CARPENTER and WYVILLE THOMSON have just concluded a remarkably successful dredging expedition in the surveying ship *Porcupine*, the scientific results of which will shortly be laid before the Royal Society. They succeeded in bringing up large quantities of ooze from a depth of more than 2,400 fathoms, and have established the wonderful facts, that at such enormous depths, in total darkness, and with a temperature below the freezing-point, there is not merely life but life in abundance; not merely the lowest organisms, but highly developed Mollusca, Echinoderms, and Star-fishes. Many practical points of great importance for future investigation have been established during this cruise, more especially the proper mechanical arrangements by which dredging can be carried on in almost all weathers, thus enormously increasing the amount of work that can be performed in a given time; and, what is perhaps of equal value, the discovery by Captain Culver of a far more effectual method than the dredge for obtaining in large numbers many of the characteristic inhabitants of these profound ocean depths. Copious series of thermometric observations have also been taken, which point to results of great theoretical interest.

THE "Female Physicians" question, thanks to Professor Masson, has made a great stride during the past week. Ladies are to be admitted to study Medicine at Edinburgh University. Imagine the feelings of the non-contents when Professor Masson, in a final outburst, described their argumentation as "rampageous mysticism, dashed with drivel from Anacreon!"

WE are glad to learn that, through the generosity of a friend of science who forbids the mention of his name, the publication of the *Astronomical Journal* is about to be resumed. Dr. Gould will edit it, as before.

THE Fellows of the Chemical Society reassemble this evening (Thursday), and begin the work of the session by discussing the President's elaborate paper on the Atomic Theory, which has been printed at length in the Journal of the Society. Any contribution to chemical philosophy from the pen of Professor Williamson must command the attention of those who have studied the history of chemistry, and the discussion he has invoked will doubtless be sustained by able supporters and opponents. Prof. Williamson holds that the atomic theory is the consistent general expression of all the best known and best arranged facts of chemistry, and he challenges detractors to bring forward an alternative theory. He asserts that all chemists use the atomic theory, though many refer to it as something which they would be glad to dispense with; and that all the facts which point so distinctly to the existence of molecules derive their significance from the atomic theory. Even those who cannot accept Dr. Williamson's conclusion that the atomic theory is the very life of chemistry, will doubtless feel duly grateful for his masterly summary of the evidence by which the theory is upheld.

WE learn with regret from *Trübner's Literary Record* that the Imperial College of Pekin, which was established to disseminate the knowledge of the West amongst the Celestials, appears to have ended in a failure. Prince Kung favoured it, but other powerful Mandarins, and amongst them Wo-Jen, a leader of the anti-foreign party, have succeeded in extinguishing it. We are afraid that we have here the result of Occidental diplomacy. Has Wo-Jen been tampered with by Lowe-king?

IT should make Englishman sad to think that while Mr. Peabody, who we trust is now better, finds the most pressing call here on his far more than princely munificence, to be the cry of the poor to heaven for bread and fresh air, in his own country, he finds the progress of Science alone needing his fostering aid. We have before us the first annual report of the Trustees of the *Peabody Academy of Science*, giving a full account of the manner in which the gift of 140,000 dollars is to be expended or invested, and of the progress already made in the buildings, natural history collections, musuems, and published proceedings, which we trust will worthily carry down the name of Peabody to posterity.

M. LOUIS LACAZE has bequeathed to the French Academy of Sciences the funds necessary for the foundation of three prizes of 10,000 francs each, to be awarded every second year. The sciences for which these prizes are to be given are Physiology, Physics, and Chemistry.

WE understand that Mr. James Young intends founding in Glasgow an institution for the study of Technology, to be opened in the course of the ensuing year.

A FRENCH translation of Professor Huxley's Elementary Physiology is announced.

WE understand that the appointment of Master of the Mint has not yet been filled up.

EARTHQUAKES seem approaching inconveniently near us. On Sunday night and Monday morning severe shocks were felt at Frankfort, Darmstadt, Wiesbaden, and Mayence; while a succession of shocks on the night of October 2, seems to have been unpleasantly violent, as the following extract from a letter from Coblentz, with which we have been favoured, will show:—"The greatest event we have had lately was an *earthquake!* It was on the night of Saturday, October 2, a little before 12, when most people were in bed, and were startled out of their sleep. I was wide awake, luckily, so came in for the whole; the noise was most alarming, and when my bed shook under me I guessed what it was. People in the town ran into the streets, and there was general alarm, as the shocks were so severe. The worst was about ten miles off, where chimneys fell and some walls cracked, but everywhere the accompanying noise seems to have been very great, like a train running under the house in bumps and jerks. The whole extent of the earthquake was very considerable, and many said they had never felt so bad a one before."

HERE are some notes from Oxford:—

On the 28th ult., the Warden and Fellows of Merton College elected Professor Clifton, F.R.S. (as Professor of Experimental Philosophy) to a Fellowship in the College. This is, we believe, only the second time that a college has availed itself of the power given by its new statutes of electing a professor to a fellowship, the person so elected being unconnected with the college in question, either by past or present membership, or by his professorship. Instances have occurred of the election of Professors to Fellowships in the colleges to which their Professorships were attached, but in this case the authorities of Merton College, without the least pressure or solicitation from without, have acted up to their increased powers given them by the last statutes, although the professorship is attached to Wadham College. We hail this piece of news with the greatest pleasure, as it indicates the desire which is now beginning to show itself, to devote the funds represented by fellowships to the purposes of University work, rather than to treat fellowships as simple prizes. The triennial elections of members of Council of the University is an important event at Oxford, as that body has sole power of initiation in University matters. The following were elected as the result of the poll on Thursday last:—The Dean of Christ Church; the Presidents of Trinity and Magdalen; Professors Price, H. Smith, and Scott; Mr. Ince, of Exeter; Mr. Liddon, of Christ Church, and Mr. Fowler, of Lincoln. The deputy appointed by Sir Benjamin Brodie to deliver lectures for him this term is Mr. A. Vernon Harcourt, of Christ Church. There are nineteen "unattached students" among the Freshmen, unattached students being persons who have availed themselves of the recently granted privilege of becoming members of the University, without becoming members of any College. Mr. Lawson, the Professor of Botany and Rural Economy, will give a course of Lectures during the ensuing term on the minute anatomy of plants. They are to be delivered in the Herbarium at the Botanic Gardens every Tuesday and Friday at 8 P.M. Is this hour fixed as the one at which it is most likely that members of the University, interested in Botany, will attend? We well remember when Prof. Lindley lectured at University College, London, to audiences of from eighty to a hundred students at 8 A.M. An election to the Lee's Readership in Anatomy will be holden at Christ Church on Saturday, December 18. Candidates for the office are requested to apply for information to the Dean on or before Saturday, the 13th of November.

AND here is a note from Cambridge:—The Rev. T. G. Bonney, B.D., Tutor of St. John's, has been appointed Lecturer in Natural Science at Cambridge; and Mr. Trotter, of Trinity, will lecture on Electricity, Magnetism, and Botany. We understand that these arrangements have been made because the staff of university professors is not large enough to do all the teaching in Natural Science that is required. We congratulate the University on the increased desire for instruction in these subjects; but is the number of men in the University competent to teach them so small that it has been found necessary to entrust Electricity and Botany to the same lecturer?

ASTRONOMY

The Astronomical Congress at Vienna

THE German Astronomical Society, although it dates from only one or two years back, is already in earnest work, and this year a Congress, extending over several days, was held at Vienna, at which not only were the president and council elected for the next year, but many papers of astronomical importance were read. Count Marshall has been good enough to send us the following account of the meeting:—The Society numbers actually 209 members, most of them superintendents of German and Extra-German Observatories; about 50 met at Vienna, among whom MM. Struve, of Pulkowa (President), Möller (Sweden), Forster (Berlin), Scheibner (Leipzig), Hersch (Neufchâtel), Lieut.-Gen. Bager (Berlin), Prof. Schaub (Trieste), Prof. Julius Schmidt (Athens), Mr. Schönfeld (Mannheim), were perhaps the most eminent. On Sept. 13, the first day of meeting, M. Struve opened the session with an exposition of the purpose of the Society and the recent progress of astronomy, especially of the knowledge of the physical nature of celestial bodies. Since the last meeting at Bonn, the number of members, the pecuniary resources, and the library have notably increased, and the following publications have been issued: Two years of the Quarterly Periodical, Dr. Auwers's paper on Variable Proper Movements, Dr. Lesser's Tables of Pomona, and Dr. von Asten's new Tables of Reduction for the "Histoire céleste Française." The study of the Asteroids, new Tables of Jupiter and of Comets, especially of the periodical ones, are in active preparation. Prof. Auwers distributed copies of tables for the reduction of positions of fixed stars from 1750 up to 1840, prepared at the Observatory of Pulkowa; and gave an account of his own new reduction of Bradley's observations, undertaken by order of the same Observatory, and of his tour to England for this purpose, during which he found, at Oxford, a number of old and very complete observations of fixed stars. The President referred to his connection with the German North Polar expedition. Prof. Julius Schmidt exhibited and explained a map of the Moon 6 feet in diameter, made at the Observatory of Athens. Prof. Zöllner (of Leipzig) detailed his recent observations of the Sun on the Janssen-Lockyer method.

September 15.—Prof. Bruhns (Leipzig) commemorated the hundredth birthday of A. von Humboldt, and distributed the prospectus of a biography of this illustrious man of science, which he intends to publish. Forty new members were admitted. Prof. Zöllner continued his lecture on his observations of the solar protuberances, and on a method of ascertaining the movements of celestial bodies by means of spectral analysis. His views were discussed by MM. Oppolzer, Scheibner, and Struve. A number of proof-prints of Prof. Heis' (Münster) stellar maps were committed to MM. Julius Schmidt and Prof. Galle, to report upon. M. de Littrow, superintendent of the Vienna University Observatory, communicated and explained the plan of the new Observatory to be built there, and commented upon the recent endeavours of some calculators of the solar parallax to derive useful results from Father Hell's observations, dating from 1769, proving these attempts to be altogether useless, by exhibiting the original diaries of this observer, and distributing fac-similes of the most important passages of them. A communication, concerning the establishment of a Humboldt Foundation at Vienna, was read.

September 16.—The president and council were elected; M. Struve, President; Prof. Bruhns, Vice-President; MM. Auwers and Winnecke, secretaries; Prof. Zöllner, Librarian; M. Auerbach, Treasurer; MM. Argelander and de Littrow, members of the Council. A new member was admitted. Mr. Julius Schmidt read his report on Prof. Heis's stellar maps. Prof. Forster read a paper concerning the solar eclipse of August 18, 1868, with Dr. Tieb's remarks on the photograms of it, taken at Aden, and proposed that the President and Council should ensure their assistance on the occasion of the next transit of Venus to any astronomers who should apply for it. The motion has been adopted. Dr. Kaiser gave an account of his observations concerning the ellipsoidal form of the Moon, and the solar protuberances, which elicited a reply from Prof. Zöllner, M. de Littrow communicated the first report of the permanent Adriatic Commission, and the programme of the prizes for the discovery of comets, lately proposed by the Imperial Academy of Vienna. Prof. Schönfeld exhibited a letter from Fabricius to Tycho Brahe (1596), in which the first notice of Mira Ceti is given, and entered into historical details concerning this variable star. The session of 1869 was closed by thanks voted to the Imperial Academy for having placed suitable localities at the disposal of the Society.

CHEMISTRY

Preparation of Uranium

M. PELIGOT has communicated to the Annales de Chimie et de Physique [xvii. 368] a short note on the preparation of uranium. A mixture of 75 grammes of uranous chloride, 150 grammes of dry potassium chloride, and 50 grammes of sodium in fragments, is introduced into a porcelain crucible, itself surrounded by a plumbago crucible. The reaction is effected in a wind furnace, at the temperature of redness; but the heat must be increased for a short time at the close of the operation. In the black slag may be found, after cooling, globules of fused uranium. Throughout the operation, it is necessary to avoid the presence both of moisture and atmospheric air.

A specimen of the metal prepared in this way by M. Valenciennes had the specific gravity, 18·33. Uranium, is, therefore, one of the densest of metals.

Stannous Chloride and Acids of Arsenic

A. BETTENDORFF has examined the action of stannous chloride on the oxygen acids of arsenic. When a solution of stannous chloride in fuming hydrochloric acid is added to a solution of arsenious or arsenic oxide in the same acid, a brown precipitate is formed, which, after proper washing and drying, consists of metallic arsenic mixed with a small quantity of stannic oxide. In an aqueous solution of arsenious or arsenic acid, stannous chloride produces no precipitate; but on adding strong hydrochloric acid till the liquid fumes slightly, precipitation takes place. Arseniferous hydrochloric acid of sp. gr. 1·182 to 1·135 gives an immediate precipitate; the same diluted to sp. gr. 1·115 gives imperfect precipitation after some time; and in a similar solution of sp. gr. 1·100, no precipitation takes place. From this it may be inferred that the reaction occurs only between stannous chloride and arsenious chloride; further, that in a solution of arsenious acid in hydrochloric acid of sp. gr. 1·115 part of the arsenic is present as chloride, but that hydrochloric acid of sp. gr. 1·100 dissolves arsenious acid as such, without converting it into chloride. The reaction above described is extremely delicate, and capable of detecting 1 pt. of arsenic in a million parts of solution. On antimony compounds stannous chloride exerts no reducing action, even after prolonged heating: hence the above-described reaction may be used to detect the presence of arsenic in antimony compounds, the solution being previously saturated with hydrochloric acid gas. Another useful application of the same reaction is to the preparation of hydrochloric acid free from arsenic: 421 grms. of crude hydrochloric acid of sp. gr. 1·164 were mixed with a fuming solution of stannous chloride, the precipitate separated by filtration after twenty-four hours, and the hydrochloric acid distilled, the receiver being changed after the first tenth had passed over, and the remaining liquid distilled nearly to dryness. The acid thus obtained gave not the slightest indications of arsenic, either by Marsh's test or by precipitation with hydrogen sulphide.—[Zeitschr. f. Chem. (2), v. 492.]

Dichlorinated Aldehyde

PATERNO has obtained dichlorinated aldehyde $C_2H_2Cl_2O$ by the action of sulphuric acid on dichloracetal. It is a liquid boiling at 89°—90°, attracts moisture from the air, and is thereby converted into a hydrate, which crystallises in beautiful laminæ, Left to itself, even in sealed tubes, it becomes dense, and changes into a white amorphous mass, which has the aspect of porcelain; but, when heated to 120°, is reconverted into the original product. Dichlorinated aldehyde dissolves without decomposition in alcohol and ether; when poured into water, it first sinks to the bottom and then dissolves, especially on application of heat; in short, it exhibits the most complete analogy with chloral. It is difficult to oxidise, its vapour not undergoing any sensible alteration when mixed with air or oxygen and passed over red-hot spongy platinum; but when gently heated with several times its own volume of fuming nitric acid, it is energetically attacked and converted into *dichloracetic acid* $C_2H_2Cl_2O_2$. Phosphoric pentachloride attacks it strongly, producing the compound $C_4H_4Cl_6O$ or $C_2H_2Cl_2O \,.\, C_2H_2Cl_4$, the action doubtless consisting in the replacement of O by Cl_2 (as in the action of PCl_5 on aldehydes in general), whereby $C_2H_2Cl_4$ is produced, which, as soon as it is formed, unites with a portion of the undecomposed dichlorinated aldehyde, producing the compound $C_4H_4Cl_6O$. The constitution of this body may be represented by the following formulæ:—

$$CHCl_2—CH_2—O—CCl_2—CHCl_2,$$

or perhaps by

$$CHCl_2—CHCl—O—CHCl—CHCl_2.$$

The compound $C_4H_4Cl_6O$ is a colourless oil, having an irritating odour, heavier than water, soluble in alcohol and ether; it distils at 250° emitting acid vapours. Alcoholic potash attacks it strongly, with evolution of heat, and formation of potassium chloride; and, on adding water to the resulting liquid, a heavy aromatic oil separates, boiling at 196°, and having the composition $C_4H_2Cl_4O$—that is to say, containing 2HCl less than the preceding. This last compound unites directly with four atoms of bromine, forming the crystalline compound $C_4H_2Cl_4Br_4O$. In this respect, the compound $C_4H_2Cl_4O$ is analogous to Malaguti's *chloroxethose* C_4H_6O, which he obtained by abstracting four atoms of chlorine from perchlorinated ethylic oxide $C_4Cl_{10}O$. According to this analogy, the compound $C_4H_4Cl_6O$ may be designated as *hexchlorinated ethylic oxide*, and $C_4H_2Cl_4Br_4O$ as *tetrachloro-tetrabrominated ethylic oxide*. The two compounds C_4Cl_6O and $C_4H_2Cl_4O$ may also be regarded, respectively, as *perchlorinated vinyl oxide* and *tetrachlorinated vinyl oxide*.—[Giornale di Scienze di Palermo, v. 123, 127.]

Colouring Matter of Wine

FR. PONCHIN proposes the use of a solution of potassium permanganate acidulated with sulphuric acid to distinguish between the natural colouring matter of wine and the various substances added to imitate that colour. For this purpose a normal solution of 2 grammes of the permanganate in 100 grammes of distilled water is prepared when wanted for use; 15 grammes of this solution acidulated, and 3 drops of pure sulphuric acid, are added to 15 grammes of normal red wine contained in a test-tube, and the liquid after being shaken is left at rest. The greater part of the colouring matter is then slowly precipitated in red flocks, while the supernatant liquid retains the same colour, without weakening, for 24 hours afterwards. After a few days, however, the precipitate acquires a deeper red colour and the liquid becomes nearly colourless. For very deeply coloured wines a larger proportion of the normal solution must be used, care being, however, taken not to add it in excess, as that would produce complete decolorisation. If, on the other hand, the same solution be added in the same quantities to wine which has been artificially coloured red, the deception will soon become apparent by the speedy decolorisation of the liquid, or by the communication of some different colour to the liquid and to the precipitate. The following table exhibits the various colours assumed by the liquid and precipitate produced under these circumstances in wine coloured by different substances—

Substances added.	*Colour of Liquid.*	*Colour of Precipitate.*
Pernambuco wood	Light orange red	Reddish yellow
Campeachy wood	Golden yellow	Orange yellow
Archil	Very light red	Reddish yellow
Laccamuffa	Very light green	Greenish-grey
Prepared Cochineal	Nearly colourless	Grey
Fitolacca	Nearly colourless	Yellowish
Myrtle	Nearly colourless	Dingy-greenish
Violets	Very light rose	Yellowish
Colouring matter of normal wine	Persistent wine-red.	Blood-red

Dye-woods resist decolorisation more strongly than vegetable juices; and Brazil wood, when treated with the above-mentioned reagent, aided by heat, acquires a crimson-red colour, due to the formation of brazilin.—[Ann. di Chim. app. alla Med., September, 1869, p. 142.]

PHYSICS

Professor Magnus on Heat Spectra.

Professor Magnus has recently contributed to the Berlin Academy a memoir on the radiation and absorption of heat at low temperatures. The results, which are of the highest importance, are essentially as follows:—

1. Different bodies, heated to 150° C., radiate different kinds of heat.

2. Some substances emit only one kind, some many kinds, of heat.

3. Of the first class, perfectly pure rock-salt is an instance. Just as its incandescent vapour, or that of one of its constituents (sodium), is solitary in tint, so the substance itself, even at 150°, emits heat of but a single ray. It is monothermic, just as its vapour is monochromatic.

4. Rock-salt absorbs heat radiated from rock-salt in larger quantity, and more powerfully, than that derived from sylvine and other kinds. It does not, therefore, as maintained by Melloni and Knoblauch, transmit heat from all sources with uniform facility.

5. The amount of absorption effected by rock-salt increases with the thickness of the absorbing plate.

6. The high diathermancy of rock-salt, does not depend on its small absorptive power for the different kinds of heat, but on the fact that it only radiates (and, consequently, only absorbs) heat of one kind; while almost all other bodies at the temperature of 150° emit heat which contains only a small fraction or none of those rays which are given out by rock-salt.

7. Sylvine (potassium chloride) behaves like rock-salt, but is not monothermic to an equal extent. This circumstance is also obviously in analogy with the incandescent vapour of the salt, or of potassium, which is known to furnish an almost continuous spectrum.

8. Heat purely derived from rock-salt is almost completely absorbed by fluor-spar. It might thence have been expected that heat radiated from fluor-spar would also be energetically absorbed by rock-salt; yet 70 per cent. of it traverse a plate of rock-salt 20 mm. in thickness. If we remember that the total heat emitted by fluor-spar is more than thrice as large as that of rock-salt, this phenomenon is readily explicable; nevertheless, it is probably dependent upon some other property of fluor-spar.

9. If a spectrum could be projected of the heat radiated at 150°, and rock-salt were the radiating substance, such a spectrum would contain only *one* band. If sylvine were employed, the spectrum would be more expanded, but still would only include a small portion of the spectrum which would be given by the heat radiated from lamp-black.

In a subsequent communication, Herr Magnus treats of the reflection of heat radiated at the surfaces of fluor-spar and other bodies.

Having succeeded in obtaining the heat from different substances at 150° free from the rays of flames and other thermogenic bodies, and afforded proof that there are some substances which emit waves of one or but few lengths, while others present them in more frequent variety, it next appeared interesting to solve the problem how bodies behave with reference to reflective power; whether, in bodies which act similarly upon light, differences parallel to those which are observed in respect of the absorption and transmission of heat do not also occur in its reflection.

Differences in reflective power are unmistakably apparent only when rays are reflected which have a uniform, or but slightly varying, length. Such rays have already been derived either from a section of the spectrum furnished by a rock-salt prism, or by transmitting the rays from a source of heat of many wave-lengths through substances which absorb a number of them. There are, however, but very few bodies that transmit rays of only one or a few wave-lengths; moreover, such rays, obtained by either method, have a very low intensity.

In spite of this difficulty, MM. de la Provostaye and Desains showed, as early as 1849, that different quantities of the heat from a Locatelli's lamp were reflected from speculum metal, silver and platinum, according as it had been conducted through glass or rock-salt; and, for reflecting surfaces of all kinds, less in the case of glass than in that of rock-salt.

Soon afterwards, by an extended series of experiments, and employing the prismatically dispersed heat of a lamp, it was proved by the same physicists that heat from the different portions of the spectrum is differently reflected. But, doubtless in consequence of the low intensity of the incident heat, their researches had reference solely to reflection by means of metallic surfaces. Now, if in rock-salt we possess a substance that emits waves of only one or but few lengths, and are acquainted with other bodies which, at 150°, also radiate but a few kinds, researches can be instituted on reflection at non-metallic surfaces. It has thus appeared that the different kinds of heat or wave-lengths are reflected from such surfaces in very different proportions. One of the most striking examples may here be adduced: it refers to the reflective power of fluor-spar.

Of the heat radiated by a great variety of substances, unequal (though but slightly differing) amounts were reflected at an angle of 45°; being in the case of—

Silver	between 83 and 90 per cent.	
Glass	,, 6 ,, 14 ,,	
Rock-salt	,, 5 ,, 12 ,,	
Fluor-spar	,, 6 ,, 10 ,,	

But of the heat from rock-salt, fluor-spar reflected 28 to 30 per cent., whereas silver, glass, and rock-salt returned no more of this heat than in the preceding cases.

Here, too, it was evident, as in the experiments on thermic transmission, that sylvine emits, besides a large quantity of the rock-salt kind, species of heat of another nature. Fluor-spar reflects 15 to 17 per cent. of the heat from sylvine; less, consequently, than that from rock-salt, and more than that from the other radiating bodies.

Granted an eye that could distinguish different wave-lengths of heat in the same manner as wave-lengths of light, and when the waves from rock-salt are incident upon different bodies, fluor-spar will appear to it brighter than any. If the rays are derived from sylvine, fluor-spar would seem still brighter than all the above bodies, but not so bright as when submitted to the rock-salt rays.

Melloni has shown that different substances transmit heat in very unequal proportions, and that the source of heat has a marked influence on the facility of transmission. Still, the sources of heat were only distinguished by degree; it was merely recognised that an increased temperature corresponds to increased variability of wave length. It now appears that at one and the same temperature, and *that*—viz., 150°—far below incandescence, different substances emit very different kinds of heat, and that, within such a range, an extraordinarily large number of different heat-rays or wave-lengths continually intermingle. This manifold intermixture is particularly furthered by the selective reflection taking place at the different surfaces.

It follows from what has been said that an eye capable of discerning the different wave-lengths of heat, as it can now discriminate the colours of light, would perceive, with very little warmth to itself, every possible variety of tint in surrounding objects.

PHYSIOLOGY

Pettenkofer on Cholera

Nearly the whole of the second part of the Zeitschrift für Biologie, bd. v. (300 pages), is taken up by a long memoir by Prof. Von Pettenkofer on "Soil and Sock-water in their

Relations to Cholera and Typhus" (Boden und Grundwasser in ihren Beziehungen zu Cholera und Typhus) in which he developes at length his views. To many these are probably now well known, but still, it may be perhaps as well to state that they are somewhat as follows.

The phenomena of Cholera result from the introduction into the animal system of a cholera poison, which is possibly an organic being, and which we may call *z*. Now, *z* is non-reproductive; does not of itself multiply or spread. But there is another distinct thing, the cholera germ (originating in India), which we may call *x*. *x* of itself will not produce cholera symptoms. It may remain, and probably may multiply in the human body, and be carried in or on the body from place to place without *of itself* producing cholera. Cholera symptoms can only be brought about by *z*, and *x* can only give rise to cholera, indirectly, by generating *z*. But *x*, in order that it may generate *z*, must come in contact with and act upon another substance, which we may call *y*. That is, *x* cannot germinate into *z* unless it meets with the substratum *y*; or we may use the idea, thrown out we believe by Dr. Farr, and imagine *x* and *y* to be the male and female parents of the offspring *z*, which is either sterile, or can only reproduce *x*.

Thus, then, *x* originating at certain times in India, and meeting with *y* at once gives rise to *z*, and an outbreak of cholera is the result. The quantity of *z* is probably more than sufficient to account for all the cases that occur; the surplus may even perhaps be carried about, and so spread the epidemic; but there being no reproduction of *z*, the stock would soon be exhausted. With *z*, however, a quantity of *x* is also carried about, more particularly by the excrement; *x*, in fact, clings to its products just as yeast cells cling to a fermented liquid. And whenever *x* meets with fresh *y*, it generates fresh *z*; and so the epidemic travels on, *x* making itself felt by *z* whenever it falls upon a store of *y*. For the existence of *y*, certain things are necessary, to wit:—

1. A soil which, like alluvium, is permeable to air and water for several feet deep.
2. A rise and fall of sock-water. A soil which is permanently dry, or one which is always filled with sock-water, are equally unfavourable for the development of *y*. The change of level of water is absolutely necessary.
3. The presence of organic and mineral matters on which the variations in the amount of sock-water may act, and out of them produce *y*.
4. A temperature suitable for such processes of organic evolution.

All these points and many others are fully discussed in a series of chapters with such headings as "Porous and Compact Soils"; "The Soil and the Immunity of Wirzburg"; "Influence of drinking Water on Cholera epidemics"; "Considerations on the Cholera epidemic of 1866 in East London, in reference to Soil and Sock-water conditions"; "Apparent evidences against the 'Soil and Water theory' and for the theory of 'Contact and Idiosyncrasy,'" &c. &c. It concludes with a series of aphorisms, "On the Origin and Spread of Cholera"; "On the Influence of Variations in Sock-level on the Enteric Fever of Munich"; and, "On the Causes of the Immunity of Lyons."

SOCIETIES AND ACADEMIES.

Zoological Society.—The first scientific meeting for the session will be held on Thursday the 11th inst., when Prof. Flower, F.R.S., will read a paper on the Anatomy of the Aard-Wolf (*Proteles cristatus*). The following communications have been received since the last meeting:—Dr. J. Anderson: Letter received from, describing a living specimen of the Pigmy hog of Terai (*Porcula salvania*).—Mr. P. L. Sclater: Remarks on the condition of various Zoological Gardens on the Continent recently visited by him, and on new and rare animals observed in those establishments.—Dr. B. Simpson. Notes on *Ailurus fulgens*.—Mr. John Brazier: Note on the Egg of a species of *Megapodius* from Bank's Islands.—Surgeon Francis Day: Remarks on fishes in Calcutta Museum.—Mr. John Brazier: Notes on the Localities of two Species of Land-Shells.—Mr. R. B. Sharpe: Additional Notes on the genus *Ceyx*.—Dr. George Bennett: Letter received from, on the habits of the Wood Hen of Lord Howe's Island.—Dr. J. E. Gray: On the Guemul or Roe Buck from Tinta, South Peru.—Dr. A. Günther: Report on two collections of Indian Reptiles.—Mr. Morton Allport: Letter received from, on the introduction of Salmon into the Australian Colonies.—Rev. O. P. Cambridge: Notes on some Spiders and Scorpions from St. Helena, with descriptions of new species.—The Secretary: On additions to the Menagerie during June, July, August, and September.—Mr. W. T. Fraser: Letter received from, respecting the Existence of the Rhinoceros in Borneo.

MANCHESTER.

Literary and Philosophical Society, October.—Mr. E. W. Binney, F.R.S. in the Chair. The following extract of a letter from Dr. Joule, F.R.S., dated Southport, October 5th, 1869, and addressed to the Chairman, was read:—"I enclose a rough drawing of the appearance of the setting sun. Mr. Baxendell noticed the fact that at the moment of the departure of the sun below the horizon, the last glimpse is coloured bluish green. On two or three occasions I have noticed this, and also near sunset that just at the upper edge, where bands of the sun's disk are separated one after the other by refraction, each band becomes coloured blue just before it vanishes."

PARIS.

Academy of Sciences, October 25.—M. L. Pasteur communicated a note relative to the dispute which has arisen between him and M. Thenard on the subject of his patented process for preserving wines by the application of heat. A paper was read by M. Phillips on the Movement of similar solid Elastic Bodies, supplementary to a memoir on the equilibrium of such bodies, read in January last.

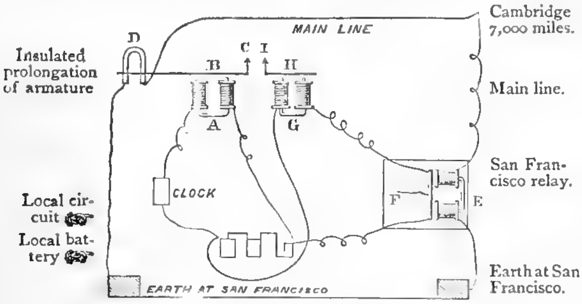
A memoir on the fundamental Equations of the mechanical theory of Heat, by M. F. Reech, was presented by M. Regnault. In a note on the illumination of transparent bodies by polarised Light, M. A. Lallemand described some new experiments with transparent solids. On passing a ray of polarised light horizontally through a polished cube of glass in a direction perpendicular to two of its faces, the maximum of illumination is horizontal, the light emitted is white, is entirely polarised in a horizontal plane, and gives the principal lines of the solar spectrum. When viewed vertically, the illumination is nil, unless the glass be fluorescent. The light observed in a vertical direction in the latter case is more or less coloured, is neutral to the polariscope, and gives none of the lines of the solar spectrum. The author noticed the behaviour of various other substances, such as crystal, fluor spar, Iceland spar, &c., M. Dumas communicated a letter from M. P. Volpicelli on the Heat of the Lunar Radiation containing an historical sketch of the researches upon this subject, and showing that both Melloni and Herschel have demonstrated the calorific action of the Moon. M. H. Marie Davy, whose previous statement (September 20, 1869) that the calorific effects of the Moon's rays were inappreciable called forth M. Volpicelli's remarks, now communicated a note on the Calorific Power of the Lunar Rays, in which, after noticing that Melloni was the first to demonstrate the existence of such a power, and that his results had been confirmed by Prof. Piazzi Smyth; he goes on to describe his own recent experiments, in which, by the employment of the thermo-electric pile, he has been able to obtain a series of results perfectly confirmatory of those of his predecessors. He found that the heat furnished by the moon is quite appreciable, and that its amount increases rapidly as it advances towards the full. M. C. Dareste communicated a memoir on the notion of Type in Teratology, and on the distribution of monstrous type in the division of vertebrate animals; the argument of which is, that the type of monstrosities is correlated with the type of organisation, so that if uniformity of type occurs in monstrosities throughout any wide range in all classes of the vertebrata, for example, the origin of such monstrosities dates from a very early period of embryonic development, and the more limited the range of a monstrosity, the later in the life of the embryo will be its origin. A paper was read by M. P. P. Dehérain on the influence exerted by different luminous rays upon the decomposition of carbonic acid and the evaporation of water by leaves. The author states that, with equal intensity, the yellow and red rays act more energetically than the blue and violet rays, both in producing evaporation, and in causing the decomposition of carbonic acid; in the latter respect he found that the leaves of *Potamogeton crispus* emitted 26·2 cub. cent. of gas under yellow light; they gave off only 5·8 cub. cent. in the same time under blue rays of equal intensity. M. E. Decaisne communicated some remarks on the various conditions of the production of goître; M. Landrin, a note on the physiological action of Chloral; M. Jaliwski, an account of a process for bronzing iron; M. Delaurier, a note on the manufacture of manganate of calcium, and M. Mehay, a note on the Infinitesimal Calculus.

PHILADELPHIA.

American Philosophical Society.—We select the following extracts from the reports of the recent meetings of this Society :—

Prof. Trego has communicated an extract from a letter from Mr. Davidson of the Coast Survey, to Mr. D. B. Smith of Germantown, detailing the method employed to obtain the recent determination of longitude and the velocity of the electric current between Cambridge and San Francisco.

"I give you the first written news not only of our telegraph longitude success, but of the success of my plan for determining the *time of transmission of clock signals from my clock to Cambridge and back*, over 7,000 miles of wire, through 13 repeaters and a multitude of relays. Through the liberality of the Western Union Telegraph Company, I had two trans-continental lines placed at my use, and last night I succeeded beautifully. My circuit was as follows. My clock breaks the local circuit every second, depriving the helix A of its electricity, and the magnet of its magnetism. This relieves the armature B, which is drawn away by a spring, and the pen C makes its record on the revolving cylinders of the chronograph. At the same instant the main current to Cambridge and back is broken by the insulated prolongation of the armature at D, and the break transmitted to Cambridge and back, through 7,000 miles of



C. Sending pen. I. Receiving pen.

SAN FRANCISCO CHRONOGRAPH.

wire, to my relay E, which relieves the armature F, and the local circuit is broken ; the helix G deprived of its electricity and the magnet of its magnetism, relieving the armature H, which is drawn away by a spring, and the pen I makes the record on the revolving cylinders of the chronograph. These two pens are on the same horizontal line. Our experiments show that it took 0·87 of a second to traverse the above circuit. I also made experiments through to Buffalo, Chicago, Omaha, Cheyenne, Salt Lake, and Virginia, and back. All successful. As this experiment was not contemplated by the programme of the longitude experiments, I have the satisfaction of seeing my ingenuity successfully proved."

Prof. Kirkwood has communicated through Mr. Chase a discussion of the periodicity of the Sun's spots. We shall return to this communication.

Mr. Dubois presented a specimen and analysis of silver ore, accompanied with the following note from the Assay Office, United States Mint :—

"In the Report of the British Commission on International Coinage, lately published, we find an extract from the *Journal des Debats*, of November 13, 1866, stating that the German assayers had found the average fineness of French gold coins of that year to be 898 thousandths, and a fraction. It adds that this is an unworthy source of gain to Government, whose ambition it should be to have the coins *correct*. The *Moniteur* of November 20 (official organ) replies, that this is as near to standard as can be expected from the defects of practical operation; and that it is the duty of Government to prevent these 'ill-founded criticisms.' Our own assays, for many years, have proved a deficiency in the French coins, averaging about one-thousandth. The apology of the *Moniteur* has no just foundation. Both at this Mint, and at San Francisco, the gold coins are kept close to the mark, scarcely varying the tenth of a thousandth ; as is proved by annual assays, and by foreign reports. British coinage is equally exact.

"This fact affords an argument against the project of International Coinage. If we work to 900, and France to 899 or less, and both pass alike, the difference is against us."

DIARY.

THURSDAY, NOVEMBER 4.

LINNEAN SOCIETY, at 8.—On some Brazilian Plants from the neighbourhood of the Campinas : J. Correa de Mello. On two Indian Plants : N. Dalzell. On the Occurrence of a Luminous Insect near Buenos Ayres : R. Trimen.

CHEMICAL SOCIETY, at 8.—Discussion on Dr. Williamson's Discourse on the Atomic Theory.

FRIDAY, NOVEMBER 5.

GEOLOGISTS' ASSOCIATION, at 8.—Comparative Anatomy as applied to Geology : Dr. C. Carter Blake, F.G.S.

MONDAY, NOVEMBER 8.

LONDON INSTITUTION, at 4.—Elementary Physics : Prof. Guthrie.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—President's Address. Journey to the Yellow River : Mr. Elias.

TUESDAY, NOVEMBER 9.

ETHNOLOGICAL SOCIETY, at 8.—On the Chinese Race ; their Language, Government, Social Institutions, and Religion : Mr. Gardner.

WEDNESDAY, NOVEMBER 10.

GEOLOGICAL SOCIETY, at 8.—Australian Mesozoic Geology and Palæontology : C. Moore, F.G.S. On some Plant and Insect-beds in New South Wales : C. Moore, F.G.S. Further Evidence of the Affinity between Dinosauria and Birds : Prof. Huxley, F.R.S. On the Dinosauria of the Trias, with observations on the Classification of the Dinosauria : Prof. Huxley, F.R.S.

ROYAL MICROSCOPIC SOCIETY, at 8.—On High Power Definition, with Illustrative Examples : Dr. G. W. Royston Pigott, F.R.A.S. On the Structure of the Scales of certain Insects of the Order *Thysanura* : S. J. McIntire.

THURSDAY, NOVEMBER 11.

LONDON INSTITUTION, at 7.30. — On Architecture, or the Fine Art of Building : Prof. Robert Kerr.

ZOOLOGICAL SOCIETY, at 8.—On the Anatomy of the Aard-Wolf (*Proteles cristatus* : Prof. Flower, F.R.S.

LONDON MATHEMATICAL SOCIETY, at 8.—General Meeting at Burlington House.

THURSDAY, NOVEMBER 11, 1869.

THE DULNESS OF SCIENCE

WE have all heard of the fox who, when he had lost his own tail, tried to prevail upon his comrades to dispense with theirs; and we think it must surely have been in a congress of the blind that the question was first started, "Is it dull to use your eyes and look about you?"

For, in fact, what is science but this? We come unexpectedly into a great mansion, of which we know nothing; and if it be dull to seek out the various inmates of the house, and to ascertain its laws and regulations, then is science dull; but if this be important and interesting, then so also is science interesting.

But, alas! the blind in this sense are numbered by myriads; and as they, for a time, almost threaten to carry their point, a few remarks upon the dulness of science, or rather, perhaps, the dulness of men, may not be out of place.

We have in our mind's eye at the present moment several notable specimens of blind men. One of these lives not very far from where we write—a most hopeless individual; we had better not inquire too narrowly concerning his occupation; he will be found somewhere in the purlieus of this great city. His one sense is the sense of gain. We remember once seeing through a microscope the animalcules of a drop of water, and we noticed that one of the largest of these had one end fixed to the side of the vessel, while its arms and mouth were busy gathering up and swallowing its smaller neighbours. Now, the man of whom we speak is only this animalcule magnified without the microscope. Ignorant of all laws, civil, religious, physical, moral, social, sanatory, he rots in his place until Dame Nature, in one of her clearing-out days, fetches at him with her besom the plague; and he is swept aside and seen no more.

Our country readers are no doubt well acquainted with Farmer Hodge. One day he happened to sit next the poet Coleridge, listening, with that reverence for his betters to which he had been early trained, to the marvellous sayings of the great man, and it was only when the apple dumpling made its appearance that he exclaimed, "Them's the jockeys for me!" Hodge, we fear, maintains no sort of relations with the universe around him. He farms in the same way in which his grandfather did, and has the most profound aversion for the steam plough.

He told Tennyson—

"But summun' ull come ater meä mayhap wi' 'is kittle o' steäm,
Huzzin' an' maäzin the blessed feälds wi' the Divil's oän teäm.
Gin I mun doy I mun doy, an' loife they says, is sweet;
But gin I mun doy I mun doy, for I couldn abear to see it."

Nevertheless, Hodge has some sense of his duty to his neighbour. Indeed, we learn from D'Arcy Thompson, that being once asked What is thy duty towards thy neighbour? he wrote as follows upon a slate:—

"My duty tords my nabers, is to love him as thyself, and to do to all men as I wed thou shall do and to me, to love, onner and suke my farther and mother, to onner and to bay the Queen, and all that are pet in a forty under her, to smit myself to all my gooness, teaches, sportial pastures and marsters, to oughten myself lordly and every to all my betters, to hut nobody by would nor deed, to be trew in jest in all my deelins, to beer no malis nor ated in yours arts, to kep my hands from pecken and steel, my turn from evil speaking, lawing and slanders, not to civet nor desar othermans good, but to laber trewly to git my own leaving, and to my dooty in that state if life, and to each it is please God to call men."

Ascending in the scale, we come next to our friend "Cui Bono;" a very good sort of man, very fussy, very philanthropic, and very short-sighted,—in fact, he sees nothing distinctly that is more than one inch from his face. He called upon us the other day to give us a little good advice: it was about the time when our astronomers were investigating the chromosphere of the sun. "What," he asked, "is the use of all this? will it put one penny in your pocket or mine? will it help to feed, or clothe, or educate your family or mine? Take my advice, sir, and have nothing to do with it." We did not reply to him; indeed we learned afterwards that he had just written an article on the subject in one of the journals. Next day he called upon us in a state of high jubilation; he had just seen a friend of his who had succeeded in making a useful application of some great discovery, which, being within the requisite *inch*, was clearly perceived by "Cui Bono"—"A very useful and practical discovery, sir, which will greatly alleviate human suffering; none of your hydrogen-in-the-sun business." And so the successful adapter got all the praise, while the wretched man of science who discovered the principle was left out in the cold.

Still ascending in the scale, we come to a man of strong mental eyesight, but without leisure to use it; one that it makes us grieve to see, inasmuch as he is capable of far better things. His ears are not altogether stopped to the mighty utterance that all nature gives, nor yet is he wholly ignorant, when at night he looks upwards, of that which the firmament declares; but its utterance is drowned in the tumult of a great city, while its starlight is quenched in the smoke. Our sentiment for such a man is that of pity; for indeed, what with the cares of this world and the deceitfulness of riches, he has a hard battle to fight.

But is it not melancholy to reflect how great a proportion of the energy of this country is devoted to the acquisition of gain, and how small a proportion to the acquisition of knowledge?

We have now arrived at the ranks of the affluent and the nobly-born, where, if anywhere, we might expect to find "tastes refined by reading and study, and judgments matured by observation and experience;" but how seldom is this the case? The mental eyesight is often weak to begin with, and often is it rendered still weaker by poring over classics without end. The unfortunate youth is then sent to make the tour of Europe. He is sent to Switzerland and the Alps to see all that is grand in nature, and to Rome and Paris to see all that is great in art, and he comes home wretched and disgusted, and no wonder. He has been made the unfortunate subject of a senseless experiment—an experiment much the same as that of turning a man with weak eyes into a picture gallery in order to improve them. His friends forget that appreciation of the beautiful and the true is the product of the coming together of two things—eyesight and nature. In fact, the result is much the same, whether a man with no eyes is carried out into a glorious landscape, or whether a man with good eyes is shut up in a dark room.

It is of this the poet speaks, when he says :—

" O Lady ! we receive but what we give,
And in our life alone does Nature live ;
Ours is her wedding-garment, ours her shroud !
And would we aught behold of higher worth,
Than that inanimate cold world allow'd
To the poor, loveless, ever-anxious crowd,—
Ah ! from the soul itself must issue forth
A light, a glory, a fair luminous cloud
Enveloping the earth ;
And from the soul itself must there be sent
A sweet and potent voice, of its own birth,
Of all sweet sounds the life and element !"

But let us hasten to our friend Philosophus, who is a man of quite a different mould. Once, when he was young, his tutor said to him, " Have the goodness, sir, to solve the following problem : 'A hemispherical bowl is filled with a heavy fluid, the density of which varies as the *n*th power of the depth below the surface ; find the whole pressure and the resultant pressure on the semi-lune of the surface contained between two vertical planes passing through the centre of the bowl, and making with each other an angle 2β.'" But Philosophus thrust the paper violently aside, saying " I will have none of that," and in fact was extremely rude. You may be sure, therefore, that when he came to be a man he had a mind of his own, and carried out his own ideas. He told us lately that he had been studying the laws of energy. It is a mistake, he said, to suppose that these laws are difficult of comprehension ; they are merely remote from our ordinary conceptions, and must be patiently pursued until you grasp them. He had studied them, he said, at all times and on all occasions—in the railway carriage, on the thoroughfare, in the study, on his bed, in the night watches ; and now that he had come to perceive their exceeding grandeur, and beauty, and simplicity, they were a source of great and continual joy to him, and recompensed him more than a thousandfold for all the trouble he had taken. Philosophus lately told us certain truths which may, perhaps, be of service to the readers of NATURE. He said that, not far from London, there was a place where the spirits and understandings of men were annually ground to pieces in a huge machine made of the very best metal ; ay, such is its temper, said he, that were it only made into good broadswords, it might enable us to cleave our way to the very heart of the universe. Again, he said : " No doubt the dulness of science is a cry of the blind ; nevertheless, men of science are much to blame. It is their sense of beauty that leads them to Truth, whom they discover by means of the glorious garments which she wears. But she is immediately stripped of these, and dressed in an antiquated mediæval garb, worse than that of any charity-school girl, and equal to that of any Guy Faux : no wonder that in such guise her beauty is unperceived by those who cannot pierce the veil, and that as a consequence she is slightly esteemed."

There was another thing he told us—a thing of the highest importance. " The priests of Science," he said, " must consent to use the vernacular, before they will ever make a profound impression upon the heart of humanity ; and when they have learned to do this, let them not fear the sneers of their deacons who will call their teaching sensational.

F. R. S.

THE ATOMIC CONTROVERSY

IT is one of the most remarkable circumstances in the history of men, that they should in all times have sought the solution of human problems in the heavens rather than upon the earth. Sixty years ago a memorable instance of this truth occurred when Dalton borrowed from the stars an explanation of the fundamental phenomena of chemical combination. Carbon and oxygen unite in a certain proportion to form "carbonic acid ;" and this proportion is found to be invariable, no matter from what source the compound may have been prepared. But carbon and oxygen form one other combination, namely, "carbonic oxide"—the gas whose delicate blue flame we often see in our fires. Carbonic oxide may be obtained from many sources ; but, like carbonic acid, its composition is always exactly the same. These two bodies, then, illustrate the law of *Definite* Proportions. But Dalton went a step further. He found that, for the same weight of carbon, the amount of oxygen in " carbonic acid " was *double* that which exists in carbonic oxide. Several similar instances were found of two elements forming compounds in which, while the weight of the one remained constant, the other doubled, trebled, or quadrupled itself. Hence the law of *Multiple* Proportions. The question was—in fact, the question is—how to account for these laws. Dalton soon persuaded himself that matter was made up of very small particles or *minima naturæ*, not by any possibility to be reduced to a smaller magnitude. Matter could not be divisible without limit ; there must be a barrier somewhere. No doubt, as a chemist, he would have rejected the famous couplet—

Big fleas have little fleas, upon their backs, to bite 'em ;
And little fleas have smaller fleas, and so *ad infinitum.*

" Let the divisions be ever so minute," he said, " the number of particles must be finite ; just as in a given space of the universe, the number of stars and planets cannot be infinite. We might as well attempt to introduce a new planet into the solar system, or to annihilate one already in existence, as to create or destroy a particle of hydrogen." All substances, then, are composed of atoms ; and these attract each other, but at the same time keep their distance, just as is the case with the heavenly bodies. The atoms of one compound do not resemble those of another in weight, or size, or mutually gravitating power. But as they are indivisible, it is between them that we must conceive all chemical action to take place ; and an atom of any particular kind must always have the same weight. The atom of carbon weighs 5 ; the atom of oxygen weighs 7. Carbonic oxide, containing one of each must therefore be invariably constituted of 5 carbon, and 7 oxygen : carbonic acid must in like manner contain 5 carbon, and 14 oxygen. Here, then, Dalton not only states that he has accounted for the two laws we have mentioned by making a single assumption ; but he evidently intends his theory to be used as a criterion or control in all future analytical results, and already views it as the birth-place of chemical enterprise.

Such, and so great, was the atomic theory of Dalton ; founded, certainly, on erroneous numbers, but containing in itself the germ of their correction ; aspiring to the command in innumerable conquests ; and setting itself for the rise or fall of the chemical spirit.

It is hardly necessary to make any detailed review of the history of the atomic theory. Berzelius made it a starting-point for researches which, on the whole, have been unsurpassed in their practical importance, and engrafted upon it his celebrated electrical doctrine. Davy and Faraday refused to admit it; Laurent and Gerhardt accepted it doubtfully, or in a much modified form. Henry declared that it did not rest on an inductive basis. There can be no doubt, however, that the atomic theory has been accepted by the majority of chemists, as may be seen on even a cursory inspection of the current literature of their science. Our present intention is to give such a summary of the atomic question as may be serviceable to those who take an interest in the discussion at the Chemical Society on Thursday last.

The modern supporters of the atomic theory agree with Dalton in the fundamental suppositions we have given above; but assert that they have a much stronger case. The phenomena of gaseous combination and specific heat have indeed changed the numerical aspect of the theory, but not its substance. The simplicity of all the results we have accumulated with respect to combining proportions is itself a great argument for the existence of atoms. They all, for example, have the same capacity for heat; they all, when in the gaseous state, have a volume which is an even multiple of that of one part by weight of hydrogen. But bodies in the free or uncombined state—such, in fact, as we *see* them—more commonly consist of many clusters of atoms (*molecules*) than of simple atoms. These molecules are determined by the fact that when in the gaseous state they all have the same volume. Again, select a series of chemical equations, in which water is formed, and eliminate between them so as to obtain the smallest proportion of water, taking part in the transformations they represent. It will be found that the number is 18; which necessarily involves the supposition that the oxygen (16) in water (18) is an indivisible quantity. To put this last point another way: hydrochloric acid, if treated with soda, no matter in what amount, only forms one compound (common salt). Now we know that the action in this case consists in the exchange of hydrogen for sodium. But if hydrogen were infinitely divisible, we ought to be able to effect an inexhaustible number of such exchanges, and produce an interminable variety of compounds of hydrogen, sodium, and chlorine; hydrochloric acid being the limit on the one side, and common salt (sodic chloride) terminating the other. No such phenomenon occurs; and, since matter must be infinitely or finitely divisible, and has been thus proved not to be the former, it must be the latter. Atoms, therefore, really exist; and chemical combination is inconsistent with any other supposition. Those who hold the contrary opinion are bound to produce an alternative theory, which shall explain the facts in some better way.

Now let us hear the plaintiff in reply.

The atomic theory has undoubtedly been of great service to science, since the laws of definite and multiple proportions would probably not have received the attention they deserve, but for being stated in terms of that theory. Yet we must discriminate between these laws, which are the simple expression of experimental facts, and the assumption of atoms, which preceded them historically, and therefore has no necessary connection with them. For it was the Greek atomic theory which Dalton revived. Nor has any substance yet been produced by the atomists, which we cannot find means to divide. If, moreover, we have no alternative but to admit the infinite divisibility of matter, even that is consistent with the simple ratios in which bodies combine; for two or more infinites may have a finite ratio. Therefore, the observed simplicity, if used as an argument, cuts both ways. Possibly we are mistaken in connecting the ideas of matter and division at all; at any rate, the connection has never been justified by the opposite side. Again, admitting the argument based on the formation of common salt, the atomic theory does not tell us why only one third of the hydrogen in tartaric acid can be exchanged for sodium; why, indeed, only a fraction of the hydrogen in most organic substances can be so exchanged. Yet, the explanation of the one fact, when discovered, will evidently include that of the other. On the whole, it appears that the atomic theory demands from us a belief in the existence of a limit to division. No such limit has been exhibited to our senses; and the facts themselves do not raise the idea of a limit, which Dalton really borrowed from philosophy. The apparent simplicity of chemical union we do not profess to explain, but to be waiting for any experimental interpretation that may arise. The atomists, in bringing forward their theory, are bound to establish it, and with them lies the *onus probandi*.

The above are a few broad outlines of the existing aspect of the atomic controversy, and may somewhat assist in forming an estimate of it. The general theoretical tone of the discussion last Thursday must have surprised most who were present. Our own position is necessarily an impartial one; but it will probably be agreed that between the contending parties there is a gulf, deeper and wider than at first appears, and perhaps unprovided with a bridge.

LECTURES TO LADIES.

WHAT is the meaning of the present stir about the "Higher Education of Women"? We have before us announcements of courses of lectures intended to be given during the coming winter to the ladies of Edinburgh, London, Glasgow, Manchester, and Bradford; and we believe that similar courses are to be delivered in several other towns. The organisations under whose auspices these lectures are to be delivered, seem all of them to have come into existence at nearly the same time. Edinburgh and Professor Masson, so far as we know, have the credit of having taken the lead in the movement; but this was only two winters ago, and none of the towns we have named were more than one year behind.

What is the cause of this sudden and wide-spread demand on the part of our countrywomen for access to a different and, presumably, a higher kind of intellectual culture than has hitherto been within their reach? Or rather, first of all, is the apparent demand a real one? Is it such as to indicate that a real step has been taken, or is likely soon to be taken, towards an improved method and a higher standard of female education in England? Or is it more reasonable to suppose that the interest now manifested in the subject will disappear in the same proportion as the novelty of it? For our own part,—after making what seems full allowance for the influence which the love of novelty, and the liking to do as other people are doing, have no doubt exerted in gaining for these "Ladies' Lectures" greater popularity, and a larger share of public attention than they would otherwise have obtained,—we believe that their rapid spread, and the success which has so far attended them, are mainly due to a serious effort on the part of the women of this country to improve their intellectual condition, coupled with the conviction of the inefficiency of the facilities for mental culture that have been hitherto open to them.

An explanation of the appearance just now of such efforts and convictions must be sought for among those facts of our present social condition which are making the Woman's Question in all its aspects one of the foremost problems of the time. It is obvious enough what some of these facts are, but we should have little confidence in an attempt to enumerate them all, and to estimate exactly their relative importance. But without undertaking to explain fully the movement under discussion, we think there are evident signs that it is a natural and spontaneous outcome of existing social and intellectual conditions, and not the result of artificial stimulus. If this view is correct, it is obvious that the importance of the movement must be judged of rather by what it indicates than by what it is,—by future results that may be hoped for, rather than by successes already achieved. Looked at in this way, it claims the serious attention and support of every one who desires the intellectual advance of the community, in order that the present opportunity may be turned to advantage, and that efficient plans of future action may be founded on the experiments now being tried with more or less of what must necessarily be temporary enthusiasm.

We venture to assume that in this, as in most other cases, the first condition of permanent success is that the object aimed at should be one in which it is worth while to succeed. If both lecturers and students are in earnest in trying to make these lectures really educational and serious, they cannot fail of producing valuable results. But this will require a good deal of determination on both sides. The most obvious, and perhaps the most serious, danger besetting the teachers, is the temptation—arising from an unconscious want of respect for their audience—to make their lectures *interesting*, instead of trying to impart the greatest possible amount of solid instruction. We confess that one or two very attractive-looking programmes that we have seen have suggested the thought, that possibly the lectures they announced might be equally well described as essays, such as constitute the more thoughtful kind of magazine articles; and that, if this were the case, it was not obvious what greater advantage would arise from their author reading them aloud to an assemblage of ladies than would result if the same ladies could be induced to read them to themselves at home.

But, though we have no reason to believe that such a criticism would be really applicable to any of the actual courses, it is none the less desirable that all concerned should be on their guard against the tendency for it to become so. Thorough teaching, and not entertainment, of however high a kind, is what we trust that every lecturer will strive to give, and every student to obtain. And, after all, the spirit and quality of these lectures will depend as much on the students as on the teachers. No doubt a thoroughly earnest teacher may do a good deal towards producing earnest pupils; but, in the long run, the kind of instruction given will be that for which there is a demand. Ladies who intend to join any of the classes now forming will not expect to get any benefit from them, unless they give up for them all other engagements, at least so far as to be able to attend with regularity. If they only go to the lectures when in want of other occupation, they had better not go at all. Moreover, we have not much faith in the educational value,—at any rate for residents in London,—of courses in which only one lecture is given in a week. There are few persons who can keep up any vivid interest in a subject which occupies their thoughts for only one hour a week; and we imagine that ladies, who are unwilling to spare the time for two lectures a week on a subject which they wish to study, will scarcely be found among the number.

In conclusion, we may remind our readers of two sets of lectures to ladies which begin this week in London: one of them at the South Kensington Museum, and the other, by Professors of University College, partly at St. George's Hall, Langham Place, and partly at University College. We heartily wish success to them all, and urge all our readers to do what they can to promote it.

GEOLOGY AND AGRICULTURE

WHEN man penetrated into Western Europe and Britain, he found the country clothed with dense forests interspersed with fresh-water lakes, peat-mosses, and bogs, relieved by few open glades, heaths, or moors. The native rocks could only be seen here and there, in crags and escarpments, sea-cliffs, river-banks, or mountain-heights; whilst herds of wild cattle, deer, and lesser game occupied the country, and afforded food to numerous beasts of prey.

In such a country, at first thinly populated, man could subsist by the chase alone, and a long period elapsed ere he added, first the horned sheep, and then the *Bos longifrons*, to his earliest domesticated animal, the dog, and thus entered on the pastoral stage of his existence.

The shepherd's life, however, although a great step in advance of that of the hunter, necessitates wandering from one point to another in search of fresh pasturage or water. The early shepherd was a nomad, while agriculture proper necessarily dates from the period of fixed residence; for, even admitting that early man might clear for himself—if not with his axe of stone, at least by the aid of fire—a tract of land suited for the growth of cereals, yet he would hardly toil for even such scanty return as he could gather from his little patch of corn, unless he had some kind of fixed habitation, and a recognised right of occupation.

In Britain the art of agriculture, and indeed of all the arts of civilisation, really commenced with the Roman occupation, but the Saxons and Danes who followed, though doubtless good soldiers, sailors, and fishermen, were scarcely less barbarous than the early Britons, and no advance was made in agricultural pursuits until after the introduction of Christianity, the members of the religious establishments, once so numerous, and into whose hands most of the landed property passed, having done much to improve the cultivation of land.

While the population was comparatively small, the amount of land under cultivation was also limited, only the better class of soils in the most fertile districts being chosen for corn, and the remainder used for pasturage or common-land; whilst large tracts of country, capable of producing abundant crops, were left wild, or still covered with woods: but as people congregated in centres of trade, the demand for corn arose and increased. Although, however, the farmer was thus encouraged to attempt the tillage of waste lands hitherto neglected, little improvement is noticeable in the method of farming until the beginning of the present century; for agriculture, like all venerable arts, has been—until very lately—strictly conservative; so much so, indeed, that many of its practices and precepts have come down to us but little altered since the days when Virgil wrote the Georgics.

But this century, so pregnant with change to all our industries, has not permitted agriculture to escape innovation; and notable among the signs of the time was the establishment, in 1838, of the Royal Agricultural Society, under whose auspices much has been done towards the removal of long-cherished and old-established prejudices, and the acceptance and adoption of numberless improvements.

The chemist has been, and indeed is still, hard at work for the agriculturist, analysing the soils on his farm, and advising him what artificial remedies to apply to improve their fertility, or to fit them for special crops. He has told him the reason why a rotation of crops is beneficial; because a green-crop, a root-crop, and a grain-crop each take different ingredients from the soil; and thus, by a knowledge of their requirements, he may apply to each that special ingredient—if not already in the land—at the period when it is required by the plant. Nor has Geology neglected to tender her aid to agriculture, by pointing out that there exists a direct relation between the soil of a given area and the subsoil upon which it rests; and that thus, by a knowledge of the geological features of a country, the farmer, in the selection of land, may not only be guided to the most permanently productive soil, but also to that which rests upon a subsoil calculated to enhance rather than depreciate its value.

Anyone who will take the trouble to examine a geologically coloured map of the British Isles, will see at a glance the general distribution, at (or *near*) the surface, of all the various geological formations, from the Pliocene and Eocene in the east and south-east, to the Granites and Trap-rocks of the west and north, with the relative superficial extent of each. But let us take a nearer view. In Britain, as in almost every country in the world, and in all latitudes, superficial accumulations of clay, sand, and gravel occur, sometimes forming a mere coating of the rocks beneath, but often of very considerable thickness, and covering large areas. The earlier geologists classed the whole of these deposits under the general name of *Diluvium*, and attributed their irregular occurrence and wide distribution to the effects of one great and universal deluge. They have, however, of late years, received careful attention from many able geologists, and it is now ascertained that they sometimes contain fossils.

Thus, some are named "pre-glacial," as marking by their animal and vegetable remains a coldly-temperate climate, and comprise marine sands and gravels, the lignite clays, and the forest-bed, with its elephant-remains, which are seen cropping out on the Norfolk coast. Younger than these, and overlying them—in Norfolk at least—come the accumulations of the "glacial" period itself, marked by the Arctic character of its fauna, its ice-worn erratic blocks, and its vast deposits of boulder-clay, often 100 feet in thickness, and covering large areas in the eastern, central, and northern counties of England. It presents most anomalous appearances, the fine clay or "till" being unstratified and mostly devoid of fossils, but containing rounded and angular fragments of rock, having one or more of their sides ground down and striated. The laminated beds which accompany the "till" in Norfolk are highly contorted, and much false-bedding and irregularity exists in their mode of deposit. To these succeed the "post-glacial" period, marked by a more temperate climate, and represented by deposits which have been formed since the land assumed its present level, or nearly so; including lacustrine and river-sediments, turf-moors, ancient forests—sometimes converted into peat-bogs, and now again reclaimed by man; valley-sediments, resulting from meteoric causes, and, in fact, all the most modern surface-deposits, including remains of man and his works.

Although what we have already said about the direct connexion between the soil and the sub-soil does relate to the regularly stratified deposits, such as the Chalk, the Oolite, Lias, New Red sandstone, &c., yet it is found by careful observation that those modern and superficial patches of clays, sands, and gravels scattered over the face of the country far and wide, take such an important part in modifying the general character of the soil, that to the agriculturists of some districts, they actually surpass in interest and importance the more regular geological formations of the country.

When the Geological Survey of Great Britain was first undertaken, more than thirty years ago, the Director-General had to consider and decide which would be the most desirable plan to pursue,—whether to show on the geologically-coloured maps these "detrital" or "superficial" deposits, lying upon and concealing the more regularly stratified formations, or only to map the latter; and bearing in mind the fact already stated, that only the most vague notions existed in the minds of the earlier geologists as to the age or origin of these later deposits, and that they were commonly looked upon as the result of the deluge; it is easy to see that there were at that time good grounds for their omission. It can, however, readily be shown that, from an economic point of view, these deposits deserve to be mapped, in the interest of the farmer, with as much accuracy as the older rocks have been for the miner.

The advantages to be derived by the farmer from the mapping of all surface-deposits—irrespective of age or mode of occurrence—are exemplified in the pages of the last number of the Journal of the Royal Agricultural Society, in which the system commenced many years ago by the Council of that Society, and carried out so ably on their behalf by Mr. Joshua Trimmer, of making reports upon the agricultural geology of lands in various districts of England, has been again resumed. In this instance, most of the reports are the result of personal inspection of the districts by Mr. H. M. Jenkins, the recently elected Secretary of the Society; who, fresh from his labours as Secretary to the Geological Society of London, has given, in addition to an insight into the methods employed for improving the land, very clear and accurate sketches of the geology of each farm over which he has gone, illustrated in each case by a shaded map, expressing

Subsoil Map. Scale—Two inches to a mile.

the nature of the subsoil, and its bearing upon both the lithological nature of the soil, and its retentiveness of moisture—this latter point having a most important bearing upon its fertility.

In illustration of the various conditions under which the surface soil is cultivated, we may refer our readers, first of all, to the recently issued number of the journal referred to. We there find, in an essay on Forest-farming, by Mr. Jenkins, that "the site of the ancient forest of Sherwood furnishes some of the best examples in England of successful farming, under circumstances of great natural difficulty. The subsoil consists of a sandy conglomerate, and is covered by a very light sandy loam of poor and hungry character. Little is yielded by it alone; and the farmer looks upon it more as a vehicle whereby he can convey fertilising materials to his crops, than as a producer of their natural food." Here we have a natural condition of virgin barrenness, forced into fertility by the most advanced appliances of agricultural science; and from this basis of natural poverty we may diverge, on the one side, into fields which, once naturally fertile, and possessing a rich store of accumulated wealth, have been impoverished, and even *denuded*, of their wealthy mantle of soil at any rate, by a very recent degradation; and, on the other side, we may find examples where the wealth and fertility of a district are being continually increased by atmospheric causes. Mr. Jenkins gives us instructive examples of both sets of conditions, in one case both occurring on the same farm, viz. at Eastburn in the Yorkshire Wold: on one portion of the farm "the higher ground exhibits a soil gradually *increasing* in strength and depth as one ascends the hill;" while upon another portion of the farm, the thickness of the soil follows a rule precisely opposite to that just noticed: "instead of the depth and strength of soil increasing with the height, the opposite is now the case. The only essential physical difference in the two cases seems to furnish the explanation of this anomaly, namely, that we now have to deal with a *wet* valley of very slight slope, the soil on the sides of which consists of the mud (or warp) deposited by the stream in times gone by; whereas, in the other case, the valleys are dry, and their slopes have been denuded of any alluvial soil which may formerly have covered them, by an agency which has also deepened the valleys and increased the pitch of their sloping sides." All these practical descriptions, the result of actual survey, show clearly that the formation of soils is not always attributable to the same cause; for we have in them clearly indicated three natural processes by which the surface-conditions have been produced—viz. (1) Soil formed from the subsoil immediately beneath; (2) Soil formed by the denudation of soil and subsoil at higher levels; and (3) Surface denuded of soil by degrading influences. The first two processes are *formative*, while the third is *destructive;* and thus in this, as in every other portion of nature's economy, we at last learn that antagonism produces equilibrium.

H. WOODWARD

VEGETABLE PALÆONTOLOGY

Traité de Paléontologie Végétale. By Prof. Schimper. (Paris, 1869. London: Williams and Norgate.)

IF asked to indicate the most suggestive discoveries in Geological Science that have been made within the last ten years, we should unhesitatingly point to that of the Eozoön,—to the unfathoming of the mysteries of the floor of the ocean,—and to the unearthing, in high Arctic regions, of forests of Dicotyledonous trees, not merely analogous in size, habit, and conditions of life, but specifically closely allied in structure to the forest trees of middle and southern Europe, Asia, and North America. The first of these discoveries carries back the history of life on the globe over a period indefinitely anterior to that which so long marked its starting-point; the second reveals a condition of life far lower than any hitherto discovered, if not the primordial condition of organized matter itself, and is the clue to the history of the chalk, the most complicated in its relations and the richest in animal remains of all known formations; whilst the third, the most simple in its outlines and the most intelligible in its facts, has hitherto checkmated every attempt to reconcile the stubborn conclusions of astronomers, in so far as these relate to the recent history of the globe, with the palæontology of a period comparatively but little antecedent to our own in a geological point of view.

Thus it is that Geology, which in its infancy was the offspring of mineralogy, chemistry, and mechanical laws, has fallen while still young under the step-fatherhood of Biology; even the superposition of strata meaning nothing, if not supported by Palæontology, since the fact that an upper stratum of rock containing organic beings of simpler structure than that it overlies is held to be sufficient proof of their original positions having been reversed, notwithstanding all appearance to the contrary. Biology, in short, supplies the weights, wheels, and pendulum of the geological clock, of which Zoology has hitherto marked the hours, and Botany, at uncertain intervals, the minutes.

Lately, however, owing chiefly to the exertions of Heer, Massolongo, and Saporta, following the footsteps of Unger, Braun and Goeppert, Botany has gained a little of its lost ground in the race with Zoology for precedence as the handmaid of Geology. The number of species collected and arranged in the cabinets of Zürich, Vienna, Breslau, &c., has been prodigious; lucky discoveries of structural specimens have thrown clear light on the affinities of whole groups of obscure fragments; and the constant association of certain leaves with certain fruits, seeds, and flowers has led to many more very probably correct, or at least approximate, identifications. As usually obtains with a science under such conditions, the publication of new species on mistaken and uncertain grounds, or on no grounds at all, has proceeded rapidly, whilst the acquisition of a real knowledge of the objects themselves has been slow. Superficial naturalists, who think they know an oak, a laurel, or a fig-leaf when they see it, but who neither really do know these, nor the multitude of other vegetables whose leaves imitate them, have boldly made fossil species of such genera; shielding themselves under the belief that, let botanists doubt as they please, they cannot contradict.

For years this state of things has gone on; the Devonian, Carboniferous, Eocene, Miocene, and Pliocene floras have been the prey of adventurous systematists; while with the exceptions of Brongniart and Lindley no naturalist eminent for his knowledge of exotic forms of vegetation has attempted a general work on fossil plants; and that these great men simultaneously broke down, is notorious. Thirty-two years have elapsed since the suspension of the "Fossil Flora of Great Britain" by Lindley and Hutton, and of the "Histoire des Vegetaux Fossiles," by Brongniart. In this interval, but one other general work of the same nature has appeared, the "Genera et Species Plantarum fossilum," by Unger, a careful compilation by a very accomplished palæontologist of Vienna; but many excellent treatises on the vegetation of individual formations have been contributed by able men, amongst whom rank especially—on the Continent, Heer, Unger, Ettingshausen, Massolongo, de Gaudin, de Sismonda, Otto Weber, de Ludwig, Goeppert, Saporta, and de Watelet, and the author of the work now under notice,—in England, Bunbury, Binney, Williamson, and Carruthers, —and in America, Lesquereux, Dawson, and Hall. The time, therefore, has fully come for a complete review of the Fossil Flora of the globe, and it has fortunately fallen into hands which in very many respects are the best fitted for carrying it out with success.

Dr. W. Ph. Schimper is Professor of Geology in the Faculty of Science at Strasbourg, and Director of the Museum of Natural History in that city, an institution which is, we are told, largely, if not wholly, indebted to his liberality and energy for its present value and condition. Dr. Schimper is further a correspondent of the Institute of France, and of the Linnæan Society of London; the best living Muscologist, and the author of a monograph of the Fossil Plants of the Vosges, and of a work on the Palæontology of Alsace. In furtherance of his object, which is not a mere compilation, but an original work, in which each order, genus, and species is to be considered in its totality as well as in its details, and to be treated of in a large and general manner, he has visited the principal museums of the Continent, and twice or oftener those of England, making a lengthened sojourn on each occasion.

It remains to add a sketch of the general arrangement of the work, which is lucid and practical. The whole will be comprised in two thick octavo volumes, accompanied by 100 lithographic plates in quarto. Of these the first volume, of 738 pages, and 50 plates, is on sale, at the extremely moderate price of 50 francs, and appears to be exceedingly well done. The commentaries on many of the involved and obscure, though prevalent orders, as Equisetæ, are in particular well worthy of an attentive study; and as a specimen of the condition of the science as Dr. Schimper finds and leaves it, and of the extreme difficulty of the subject, we give an analysis of the contents of one tribe of this order; namely, the Calamiteæ. Of these he retains the nine following genera:—

1. *Calamites*, with seven supposed good species, under which species of three other genera are brought, with twenty-six synonyms, of which fourteen belong to one species alone; and there are, besides, nine doubtful species of the genus.

2. *Calamocladus*, with five species, under which are brought plants previously referred to no fewer than *nine other genera* (two species having respectively seven and eight synonyms).

3. *Calamostachys*, with five species, some of which have been referred to three other genera.

4. *Huttonia*, a monotypic genus.

5. *Macrostachya*, with one species, rejoicing in seven synonyms, of which four are generic.

6. *Bornia*, with three species, of which one has six synonyms.

7. *Sphenophyllum*, with seven species, having thirty-two synonyms amongst them, besides three doubtful species.

8. *Annularia*, with six species, having twenty synonyms, and including plants previously referred to six other genera.

The ninth genus, *Aphyllostachys*, is altogether doubtful.

It needs indeed a bold systematist to attack such a chaos as this reveals, and an able one to deal with it effectively and well.

The work will consist of three parts :—(1) an introduction ; (2) a botanical classification of all known fossil plants ; (3) a synopsis of them in geological sequence ; with a Bibliographical Index.

The introductory part is very full, and is comprised in ten chapters :—

Chap. I.—Historical sketch.
Chap. II.—On the state of preservation of fossil plants.
Chap. III.—Distribution of fossil plants in different formations.
Chap. IV.—Different modes of preservation.
Chap. V.—Principles to be followed in the determination of ossil plants.
Chap. VI.—Of the changes which have taken place in the vegetable kingdom from its first appearance up to the present time.
(§ 1.) Disappearance of species ;
(§ 2.) The renewal of floras by the appearance of new types.
Chap. VII. General *coup d'œil* of the floras of different geological periods.
(1.) First epoch. Reign of the Thalassophytes.—(2.) Second epoch. Reign of the vascular Cryptogams.—(3.) Third epoch. Reign of the Gymnosperms. Appearance of Monocotyledons.—(4.) Fourth epoch. Reign of the Angiosperms. (*a*) First period ; Apetalous plants. (*b*) Second period ; Dialypetalous plants. (*c*) Third period ; Gamopetalous plants.
Chap. VIII.—Application of vegetable palæontology to the climatology of the old world.
Chap. IX.—Application of vegetable palæontology to geology.
Chap. X.—General classification of stratified rocks.

Of the above chapters, the sixth, which deals with the renewal of floras by the appearance of new types, will be the first to be read by many, naturally eager to ascertain the views of so able and so unprejudiced a naturalist as Prof. Schimper, on the subject of the Origin of Species. In this matter his views are explicit, and he sums up his reasons for adhering to the doctrine of evolution in the following terms :—

In spite, then, of the deficiency of palæontological documents, we cannot mistake the general line which Nature has followed through the various geological epochs, from the first appearance of organic beings to the period of their present development. This line may be termed one of evolution, because it marks a progressive change from inferior to superior, from simple to compound, precisely similar to that of every individual with a complicated organisation. All agree that the latter is the result of a continued series of metamorphoses. Every organised being begins as a simple cell ; the embryo itself being a complex organism derived from the generating cell ; wherefore there are naturalists who trace the individual back to the cell. We know, in fact, that each living vegetable cell can give birth to a new individual, of which it is in a certain sense the first representative. Many species of vegetables and animals do not rise above this simple cell ; as soon as this has given birth to a second cell, the latter becomes in its turn a fresh individual. Whenever the derived cells remain united, so that a sort of solidarity is established amongst them, the being which is born from this agglomeration is a complex being. It will be so much the more perfect, it will occupy a step so much the higher in the scale of organisms, as the differentiation of functions produced by the metamorphosis of the cells is more complete, and the organs applicable to these functions are more independent of each other.

Has Nature followed this plan in her organic kingdom? From all that we know, I believe that we are justified in such a conclusion. The only unicellular fossil plants with which we are acquainted are the Diatoms, which have left their siliceous shells in the most ancient of fossil beds. The cellular plants of the family of Algæ are doubtless rare in the palæozoic formations ; with the exception of some little epiphytal fungi, no terrestrial cellular plants have been discovered, either in palæozoic or in mesozoic beds ; this class is even but meagrely represented in the tertiary flora, which has nevertheless much affinity with that of the present day. Nevertheless, these scanty remains suffice to convince us that, if the cellular plants which were to prepare for the arrival of vascular plants have not left numerous and striking traces, they have none the less existed, and doubtless since the earliest periods. The first vegetation on the lands which had just appeared above the waters must have been composed of cellular plants, of Confervæ, of *proembryos* or *prothalliums* of a lower or higher order of Cryptogams, as may be seen at the present day on recently reclaimed land.

The terrestrial vegetation of the Silurian epoch and of the commencement of the Devonian having left no trace, it is impossible for us to judge what were the forms of the plants which then covered the reclaimed land. All that we know is, that the primeval ocean was peopled by a numerous fauna during thousands of centuries before the appearance of vascular cryptogamic acrogens : similarly, if the Thalassophytes of those distant epochs had left no trace, their existence would be none the less infallibly proved by that of the animals whose food they formed.

The rapid glance which we are about to give of the general character of the floras which have succeeded each other on the surface of the earth, from the Devonian period up to the present time, will show better than any reasoning the progressive march which they have followed, and the close links by which they are united to each other.

J. D. HOOKER

HARCOURT AND MADAN'S PRACTICAL CHEMISTRY

Exercises in Practical Chemistry. By A. G. Vernon-Harcourt, M.A., F.R.S., Sec. C. S. ; and H. G. Madan, M.A., P.C.S., Fellow of Queen's College, Oxford. Crown 8vo., pp. 350, 66 woodcuts ; 7*s.* 6*d.* (Oxford : Clarendon Press, 1869.)

WE are glad at last to welcome a really scientific work on Practical Chemistry. Professor Harcourt and Mr. Madan have earned the warm thanks of all interested in the teaching of the science by the publication of their volume. Almost all former works on practical chemistry have been contented either to act the part of illustrated catalogues of chemical apparatus, or else they consist of cut and dried receipts for following out a system of qualitative analysis by reference to a complicated series of paragraphs, ingeniously arranged to bewilder the unfortunate student as much as possible, or they place in his hands tabular statements of reactions which have to be worked through almost always without rhyme or reason.

Mr. Madan's Ten Commandments, or "Memoranda," placed at the commencement of the volume, might well be printed in letters of gold in every laboratory, and repeated as the morning lesson of each first year's student. "Cleanliness," he begins, "stands at *the head* of the *chemist's* scale of virtues." No better advice can be given : if a student can work neatly, he is almost sure to work well. Only rarely can the "messy" beginner be trained to habits of exact experimentation and accurate thought. The second ordinance is equally important : "Do not work in a hurry. What is expended in time is often gained in power and grasp of a subject. Yet, on the other hand, learn to be economical of time." The main object of a certain class of students seems to be to get "through" with their experiments, no matter how clumsily they manipulate, or how small and incomplete may be their knowledge of what the experiment teaches. They are satisfied to have "done the thing," and if they do not obtain the required result, they either think that something in nature has gone wrong, or that the author of the book is fibbing, and they are the last to imagine that they are themselves to blame; it is sufficient for them to have tried—or rather not tried—and they pass willingly to the next operation, most probably again to court defeat. To these the only cure is to act upon the advice, "Do not hurry." Another class of persons, to whom the second part of these "Memoranda" specially applies, are those who confine all their powers to waiting; thus they watch the slow filtration of a single gelatinous precipitate, and with a kind of dreary pleasure either dream away their time, or (more commonly) annoy their more diligent neighbours, thinking that nature is invariably slow to move, and that patience is the only virtue they need to cultivate. These must be made to learn that economy of time is a necessary part of the chemist's duty, and that he, "in spite of the proverb, may do more than one thing at a time by allowing things to do themselves." The chemist's third commandment is fairly given as, "Be economical of materials." Who that has seen beginners work does not value this recommendation? Many seem to think that the more they deluge the substances they have to examine, first with acids, and then with alkalies, the more likely are they to discover the philosopher's stone, or to find their needle in the bottle of hay! How long some students take to find out that every molecule of acid or alkali, added above the required quantity, serves only as a blind to their reactions, and is in reality a most wilful adulteration of their material, with perhaps several thousand times its weight of dirt! "Never begin an experiment," says Mr. Madan, in his fourth article, "until you have looked over all the preparations for it, to make sure that you have everything within reach;" and we would make this advice apply not only to test-tubes and gas-jars, but to the mental preparation also. No experiment ought to be made until the student knows what he is going to do. He must either read a description of what he is to do, or he must see the experiment performed by his teacher; and, above all, he ought to be aware of the theoretical explanation of the changes he is about to witness. The writer for one does not think that laboratory instruction cannot be valuable, unless the student has already acquired a certain knowledge of the subject by attendance on lectures; but the theoretical instruction must then of necessity accompany the practical tuition. The very first experiment which the beginner may make—viz. that of heating oxide of mercury in a test-tube—must be the occasion for an explanation of the laws of definite combination by weight, for a statement of the numerical exactitude of all chemical change. Exercises must at once be given, and continue to be given, in illustration of these laws; and thus from the first the student must be made to grasp the facts of the exact nature of the science. He must be disabused at once of the notion of some who, when they enter the laboratory, "look upon chemistry as a mere amusement, as a means of getting up a few explosions, creating a few unsavoury smells, producing a few striking changes of colour." Unless practical chemistry is taught with these aims, in a manner calculated to afford an exact mental discipline, it is worse than useless. If the student does not cultivate habits of attention, close observation, and patient inquiry, he can gain nothing from laboratory work; on the contrary, he becomes negligent and impatient, he does not care to look for what is going on, and instead of gaining immensely, as he ought, in habits of self-reliance, he loses all confidence, finds physical science a delusion and a snare, and returns (if he has any taste for learning at all) to the more congenial path of literature.

The volume in question will much aid those who teach with this view, and it will afford still more active help to those who, possessing no teacher, have to learn for themselves.

The descriptions of the simpler operations of glass-working in the beginning of the volume, and of the construction of tube apparatus, are clearly given; and these pages are, of course, especially interesting to the self-educated student. The exercises on solution, precipitation, filtration, and distillation, are described with care, and the examples well chosen. It is very difficult to know how far such descriptions should go as regards details. The description of the manufacture of lime-water is as clear as that preparation ought to be. But is such detail needed where a word of explanation can be given? This shows the impossibility of writing a book on practical manipulation exactly fitted for all classes of students.

In the second section, on preparation and examination of Gases, we miss the theoretical explanations which, as we have said, must accompany the practical and manipulating directions; nor do questions, numerical or otherwise, accompany the exercises. This is to be regretted: a book especially written for those who work alone should contain a series of examples such as we find in many of the smaller manuals. With this exception this portion of the book is as good as need be. A chapter on the preparation of Reagents in use in the laboratory is especially valuable to the self-taught student. The solutions are made according to system; and in the preparation the student is familiarised with the metrical system of weights and measures: whilst under each heading the tests for the purity of the reagent are given; thus:—

Barium Chloride ($BaCl_2$ in 20 c.c.). Dissolve 12·2 grms in 80 c.c. of water, and dilute to 100 c.c.

The purity of the salt may be tested as follows. Place about 5 c.c. of the solution in a test-tube, heat it nearly to boiling, and add a slight excess of dilute hydrogen sulphate. While the precipitate of barium sulphate is subsiding, get ready a filter (of Swedish paper), wash it two or three times with warm water, then filter off the barium sulphate and evaporate the filtrate to dryness on a clean watch-glass. No solid residue should be left.

The authors, in their introduction to Qualitative Analysis, commence with the study of the acid radicles instead of the metals. This is, perhaps, the more scientific order of procedure than that beginning with the reactions of the metals; but we must take leave to doubt whether it is so simple, or so likely to conduce to the clear understanding of the reactions as the other older and more usually employed method.

The nomenclature used throughout the work possesses one amongst many advantages over the others (unfortunately too numerous) now in use, in that it is identical with that now employed in Germany. Surely it is a matter of some importance to assimilate as much as possible scientific nomenclature in all languages.

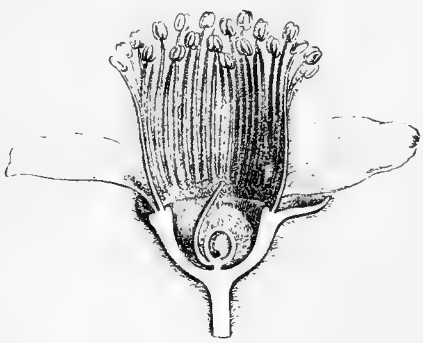
H. E. ROSCOE

BAILLON'S HISTORY OF PLANTS

Histoire des Plantes. By H. Baillon. Vol. I. 8vo, 488 pp. With 503 figures by Faguet, price 21*s.* (Paris and London: Hachette and Co.)

THIS is a fine book—a very fine book, one might say; nevertheless, not wholly satisfactory. Turning over its pages we feel a sense of power wasted in an attempt to bring together too much in a digested form,—far more indeed than any one cares to find in one work. The book, if it goes on, will be a sort of Botanical Encyclopædia, suited rather for adepts and advanced students than for the general reader. No one thinks of turning to an Encyclopædia for the best and most exhaustive information upon anything, and so it will be in this case. M. Baillon brings together Organogeny, Structure, and Taxonomy, including a description of every genus of Flowering Plants. Now this is too much for any single mind to work out. M. Baillon is a man still young and vigorous, and of wonderful assiduity; and if he live, it is quite possible he may bring his work to a close. And it will be no mean monument, though not without its warning, especially to those whose ambition impels them to aim too much at leaving behind a name in large characters rather than deeply cut. As yet, however, our author is hardly out of shallow water. Nearly all the groups which he has touched upon have been quite lately worked up systematically by other eminent botanists, and their material has doubtless afforded him a good bottom.

This first volume consists of a series of Monographs of the following Natural Orders: Ranunculaceæ, Dilleniaceæ, Magnoliaceæ, Anonaceæ, Monimiaceæ (including Calycantheæ), and Rosaceæ. We do not find any general clavis or table of sequence of the Orders, but, from the order followed so far, it would seem as though the characters of the primary divisions of Dicotyledons, usually accepted as most convenient by systematists, depending on the absence or presence of adhesion between the inner and outer whorls of the flower, were regarded as subordinate to characters based simply on cohesion or its absence between the carpels forming the pistil. All the Orders enumerated, and those in the first part of Vol. II. already published, are essentially apocarpous. Four of



CHRYSOBALANUS ICACO (Section of Flower)

them have perfect flowers and hypogynous insertion of the floral whorls; one (Monimiaceæ) is mainly imperfect and monochlamydeous; and Rosaceæ are perfect and perigynous. Now a new system is very apt to be a great bore. Nobody knows what is coming next, nor where to look for a thing; and in the present state of knowledge, in such secondary matters as the mere sequence of Orders, it is better to sacrifice the expression of a supposed affinity by a new juxtaposition in linear series, for the sake of a uniformity with accepted plans of arrangement, which have been tested many years, are widely used in the

CHRYSOBALANUS ICACO

best books, and which adventurers are too glad to fall back upon when they have sense to know when they get out of their depth.

However, waiving all this, let us do M. Baillon the justice to say that he here puts on record many original observations of great value: he is very clear, and, like many of his countrymen, has a neat way of putting things: his pictorial illustrations (in woodcut) are admirable and well-selected, as the accompanying examples will show; and, as we have said above, he is making a very fine book.

By way of sample of the work, let us take a small Natural Order: Magnoliaceæ, the Family of the Magnolias and Tulip-trees. First of all we have the Order divided into what M. Baillon calls *Series*, which, in the main, answer to the Tribes or Sub-orders of other writers. *Canelleæ* we notice is one of these: a group maintained of ordinal value, by Messrs. Bentham and Hooker, near to Bixineæ, on the ground of their syncarpous ovary and parietal placentation,—characters which M. Baillon estimates as analogous, in respect of their departure from the Magnolioid type to the similar conditions of *Monodora* in relation to other Anonaceæ. A good description, with capital figures, is given of what the author treats as type-species of the genuine Magnolias, the beautiful *M. grandiflora.* He has been at considerable pains to examine for himself the curious changes undergone by the ovule in maturation, publishing an account of it in "Comptes Rendus," lxvi. 700, apparently ignorant of Prof. Asa Gray's exceedingly clear and detailed account of the same, given twelve years ago in the Journal of the Linnean Society, ii. 106. The old genera *Talauma*, *Manglietia*, and *Michelia* are all sunk in *Magnolia*, which genus, with *Liriodendron*, constitutes the series Magnolieæ. The three former genera are very briefly disposed of, and whether specimens of each have been examined, is by no means clear. After describing successively the structural features of each Series, M. Baillon gives us a short historical summary of the Natural Order, then he discusses the points in which all, or nearly all, of the genera agree. The only three absolutely constant characters are: the woody stem, the alternate leaves, and the presence of albumen in the seeds. A triad, equally constant, we may remark, in many other Natural Orders, just as flour, suet and salt, may be common to every different sort of pudding. Eight characters are generally prevalent, the exceptions being few or solitary; these refer to the form of the receptacle, concave only in two genera, which same pair are the only exceptions to the otherwise constantly double perianth; polypetaly; direction of the micropyle of the ovule; apocarpy and placentation; stipulation. These we might speak of as the currants, and peel, and spices, and brandy, and what not, which, judiciously blended with the constituents afore-named, give special character and pre-eminence to plum-pudding. Technical diagnoses of the five Series follow. Then we have the histology of the wood and bark; a discussion of the affinities of the order; a paragraph on its geographical distribution; an account of the properties and uses of various species; and lastly, technical descriptions in Latin, of each genus, as maintained by M. Baillon. These technical descriptions, if given at all, should be accompanied by a distinct generic synonymy. It is too much to expect every one to turn back to pages so and so, and unravel it for himself, where the mention of it may read as merely incidental.

D. OLIVER

FICK ON THE TRANSFORMATION OF FORCE

Die Naturkrafte in ihrer Wechselbeziehung. By Adolf Fick. (Würzburg, 1869. London: Williams and Norgate.)

PROFESSOR FICK, who has recently been moved from Zurich to Würzburg to fill the chair of Physiology there, vacant through the untimely death of Von Bezold, is well known not only to physiologists by his many excellent researches, but also to a far wider circle through the now well-known experiments on muscular physics carried out by himself and Wislicenus. In these six popular lectures he attempts to carry an intelligent and attentive audience, not possessing special scientific knowledge, swiftly through the great story of the transformation of force, showing them, in a quiet, lucid way, how the parts are played on those two great stages, the macrocosm of the universe and the microcosm of the human body.

The first four lectures are given up entirely to the consideration of the correlation of purely physical forces. Starting from simple facts about heat, the author works his way through heat as a mode of motion, through concrete conceptions of molecular movements in changing bodies, to the general doctrine of the transformation of force and the numerical relations between one force and another.

In his fifth lecture, treading upon his own ground, he shows that the microcosm is but a stage where forces shift and change; and that no exact researches have at present in any way shown the necessity of believing that in the living body there exists any new force besides those at work in the world around. He is careful to point out that no thoroughly satisfactory balance sheet of the forces that come to and go out from a living body has yet been shown, so difficult is the task; but, though the details have yet to come, the general principle gains daily confirmation. Human force is but a transformation of chemical force, and man steals oxygen to do his work. Plants unburn what the animal burns; and so the heat of the sun brings back oxygen to the world.

And this leads the lecturer in his last lecture to the question, How does the sun get his heat? After quoting and discussing Mayer's hypothesis of the feeding of the sun with meteors, and pointing out the next question, "Whence comes the force which drives the meteors?" he finishes by dwelling on Clausius' theory of the constant loss of force in the shape of heat that cannot be weaned back to any other mode of motion, and on the general conclusions that may be drawn from it. These we prefer to give in his own words:—

If, then, when mechanical force passes into heat, *some* of that heat can never be brought back to be mechanical force, and if the change from mechanical force to heat be ever going on, all the force in the universe must at last take on the form of heat. But if that be so, then at last all differences of temperatures must disappear, and everything end in a universal Death. The whole chain of Cosmic events must therefore be looked upon not as formed of cycles, so that, cycle sweeping round upon cycle, the universe stands for ever the same, but as being a process of Evolution striving towards an End.

We are come to this alternative: either in our highest, our most general, our most fundamental scientific abstractions, some great point has been overlooked; or the universe will have an end and must have had a beginning; could not have existed from Eternity, but must at some date not infinitely distant have arisen from something not forming part of the chain of natural causes, *i. e.* must have been *created.*

M. FOSTER

OUR BOOK SHELF

Theoretical and Applied Mechanics, *for Schools, Colleges, Candidates for University Examinations, &c.* By R. Wormell, M.A., B.Sc. (London: Groombridge and Sons.)

WE are glad to see London University graduates recruiting the ranks of educational writers. Mr. Wormell states in clear and concise language the principles of elementary Statics and Dynamics, in close accordance with the syllabus of requirements for passing the examinations for the B.A. and B.Sc. degree at the London University. He gives hardly more nor less than this, but avoids at the same time an error into which most of our writers on the subject fall, viz. the overcrowding of their books with problems, which the purely didactic portion of the book does not enable even the gifted student to solve. Mr. Wormell adds to his test a great variety of really instructive *solved* problems, which will go far to help the student in finding the solutions of those given with the numerical answers alone. We have no doubt that this excellent little work will be a great success, but we should like the elementary principles of dynamics more amply illustrated. The introduction of the principle of limits on several occasions is highly commendable: the student should make its acquaintance early, but we believe in the old methods of proof to bring the matters more home to students, although they start, in a scientific view, from an inconsistency.—B. L.

Geodesy.—*Studien über höhere Geodasie.* By Dr. C. Bremiker. (Berlin, 1869.)

FROM great scientific undertakings, such as geographical expeditions, or geodetical, geological, and magnetic surveys of large areas, mankind generally derives, besides the utility of the work itself, a vast amount of contingent benefit. The result forms not only a landmark of scientific progress, but the work serves also for applying and testing a number of antecedent theoretical or practical discoveries, for separating what is sound from the unsound, and finally it rouses contemporaneously the mental energy of those more or less intimately connected with it to new exertions.

Of such a wide bearing is the great European arc-measurement now in progress, in which for the first time the curvature of parallels of latitude will be simultaneously determined with that of the meridians, and the question will be decided whether the figure of the earth, as represented by the surface of the ocean, is really an ellipsoid of rotation, or whether a triaxial ellipsoid will have to be substituted for it. Of the mathematical, physical, and geodetical investigations, which the progress of this great work has already created, Dr. Bremiker's ranks among the foremost. It discusses the methods of reduction with reference to deviation of the plumb-line, latitude, azimuth, difference in longitude, latitude, and azimuth, small angles, deduction of triangles; and employs everywhere practical and interesting formulæ. The mathematical attainments necessary for understanding this excellent little work are not too high, and we feel certain that nobody who takes an interest in higher surveying will read it without extending his experience and knowledge. B. L.

Our Bodies. By Ellis A. Davidson. (London: Cassell, Petter, and Galpin.)

WE cannot highly commend this little book, though we would wish to speak well of its author. He is evidently a thoroughly good and earnest teacher; and we have no doubt his oral lessons are far better than his written book, which may be described as "Goody Lessons in Physiology, written in words of either one or of more than five syllables." It consists of many terribly stony technicalities floating in a mass of very pappy information. On one page we find children warned, on physiological grounds, not to crack hard nuts with their teeth, and on another a description of the *axis-cylinder* of *nerves*, the *white Substance of Schwann*, and the *canaliculi* of bone. When will popular teachers of physiology and anatomy find out that these sciences are best taught free from technical hard nuts which splinter the enamel of the mind and worse? In not a few respects, too, we observe that "our bodies" of Mr. Davidson are not the same as *our* bodies.

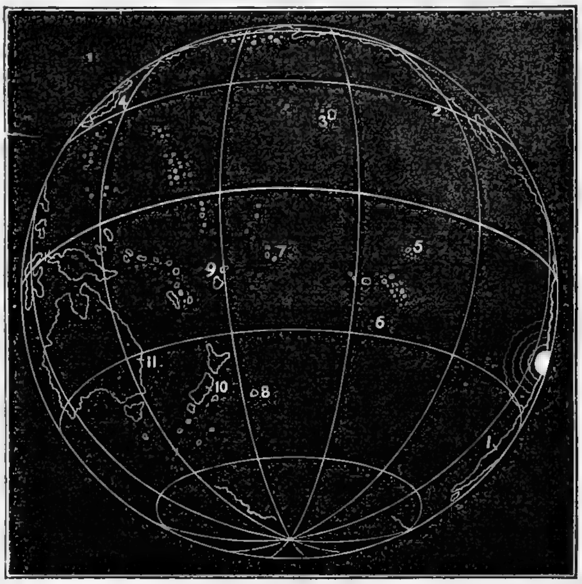
The Intelligence of Animals.—*From the French of Ernest Menault.* (London: Cassell, Petter, and Galpin.)

THE intelligence of animals may be studied in a scientific or in an anecdotal manner. M. Menault has chosen the latter method. We have not been led to form a very high opinion of his physiology or of his general philosophy; but he has compiled a most entertaining volume, crammed with most amusing stories about all kinds of animals, from ants to ourang-outangs. It is illustrated with numerous pictures, some of which are as good as the stories.

EARTHQUAKE WAVES IN THE PACIFIC

UNLIKE their great rivals, the Himalayas, which seem to have upreared themselves to a position where they can remain at rest, the Andes are disturbed from time to time by tremendous throes, whose effects are sometimes felt over a full third part of the earth's surface. To this class belonged the earthquake of August 13–14, 1868, and in many respects it was the most remarkable of all the great earth-throes which have desolated the neighbourhood of the Peruvian Andes. As in the great earthquake which overthrew Riobamba in 1797, a tremendous vertical upheaval seems simultaneously to have affected a region of enormous extent. But terrible as were the direct effects of the first vertical shock and the others which followed, it was the action of the earth-throe on the ocean which caused the greatest devastation. It is hardly necessary to recall to the reader's remembrance the fearful effects experienced at Chala, at Arica, and at other places along the Peruvian shore; for few, doubtless, have forgotten how a countryman of our own described the ominous retreat of the ocean, and the overmastering fury with which it rushed back and swept far inland, destroying at once the shipping it carried with it, and the buildings which it encountered in its course.

So fearful a disturbance of the seas around the Peruvian shores could not but generate a widely-extended oscillation of the waters of the great Pacific Ocean. Yet



it is impossible to hear, without surprise, of the enormous waves which reached the far-off shores of the islands which lie scattered over that enormous ocean-tract. The accounts which came gradually in of waves which had swept past Honolulu and Hilo, into the ports of Yokohama and Lyttleton, and had even disturbed the waters which surround the East Indian Archipelago, seemed at first scarcely explicable as the direct results of a disturbance occurring so many thousands of miles from those places.

But when the accounts are carefully compared together, they are found to point most clearly to the South American shores as the true centre whence the great wave of disturbance had spread over the whole surface of the Pacific. Professor von Hochstetter* has brought together all the accounts which seem to throw light on the progress of the great earthquake-waves from Arica. For the most part, unfortunately, the waves visited the islands and ports of

* Petermann's "Geographische Mittheilungen," part vi. 1869.

the Pacific by night; but still enough evidence remains to exhibit with sufficient clearness the course which the disturbance followed.

Let us first endeavour to form a clear conception of the scene of this great manifestation of Nature's powers. The Pacific Ocean is not commonly chosen as the subject of a single map, and the maps in our ordinary atlases are not calculated to give clear ideas respecting the true shape and dimensions of an ocean which is undoubtedly the most remarkable physical feature of the whole terrestrial globe. I have endeavoured to remedy this defect by the accompanying chart, which represents a perspective view of that half of the globe to which the Pacific belongs, and will serve, I think, to convey a tolerably clear impression of the true proportions of this great ocean.

Near the shore of Peru I have marked the estimated region of central disturbance by a white circle.

The great waves which came surging onwards from the centre of disturbance must presently have lost their circular figure. On account of their enormous dimensions they "felt the bottom," so to speak, and were more or less retarded according as they traversed shallow or deep portions of the great ocean.

At Arica the first great shock of the earthquake was experienced at about five in the afternoon of August 13th. Twenty minutes later an enormous wave fifty feet in height swept in over the shores; and we may assume that about this time the waves which were about to traverse the Pacific started on their vast career.

Along the coast of Chili the wave travelled southwards, reaching Coquimbo three hours after the catastrophe at Arica. One hour later the wave had reached Valparaiso; and yet an hour later the inhabitants of Valdivia—marked (1) in the map—were terrified by an inrush of the sea which threatened to destroy their town.

Northwards from Arica the progress of the wave was not so carefully timed. On the 14th of August, but at what hour is not stated, the shores of Lower California, near San Pedro—marked (2) in the map—were swept by a wave no less than sixty-three feet in height.

At midnight of August 13-14, the sea-wave reached the Sandwich Isles (3), and from that time until the 16th of August the sea around those islands rose and fell in a surprising manner. It appeared as though the islands were first slowly raised as by some irresistible subterranean forces, and then suffered to subside until they seemed about to disappear for ever beneath the waves; nor was it easy to believe that in reality the sea alone was in motion.

Yokohama (4) was visited by the wave on August 14th, but unfortunately the exact hour is not known, otherwise there would have been the means of ascertaining how long a wave takes in traversing nearly a complete half of the earth's circumference.

The Marquesas Isles (5) were visited by waves of enormous dimensions before midnight of August 13th. Some of the islands of this group were indeed completely submerged by the crests of the principal waves.

At Opara (6), the coaling-station for steamships plying between Panama and New Zealand, nine waves came in one after the other, at intervals of twenty minutes, the highest sweeping over the coal depot.

At half-past two on the morning of August 14th, the watchman in Apiu, on the island of Opolu (7), aroused the frightened inhabitants from their sleep with the cry that the sea was coming in upon them; and during the whole of that day the sea rose and fell at intervals of only fifteen minutes. But the waves reached the Chatham Islands (8), though nearly as far from Arica, an hour and a half sooner. Three enormous waves rushed in upon these islands, one of which, the low-lying Tupunga, was completely submerged. Between two and three hours later the wave had reached the Fiji Islands (9).

The shores of New Zealand, and especially those bays of the southern island which face towards the east, were visited by enormous waves. Between three and four o'clock in the morning, the harbour of Lyttleton (10) was left completely dry by the retreat of the water, which did not return until more than an hour had elapsed. At five the water began again to retreat, reaching its lowest point an hour later. But at a quarter-past seven and at half-past nine, and again at eleven, a great sea-wave swept over the bounds of the harbour.

Lastly, the ocean-wave visited the Australian shores near Newcastle (11) at about half-past six in the morning of August 14th, the waves gaining in height at each return until about half-past eleven, from which hour they slowly subsided.

The chief interest of these results lies in the circumstance that they enable us to form an estimate of the depth of the Pacific Ocean. Airy, Whewell, and other eminent mathematicians have shown how the velocity of sea-waves varies with the depth of the part of the ocean they are traversing. Where the breadth of the waves is great, as in the tidal wave, a very simple law connects the variation of the velocity with that of the depth. If a wave travels twice as fast in one part of its course as in another, it may be assumed that the depth of the ocean is four times greater in the former than in the latter part of the ocean. A tripled velocity signifies that the depth is nine times greater, and so on. With waves of different breadth the law is slightly different. But the following table, extracted from a larger one in Airy's paper on sea-waves (*Encyclopædia Metropolitana*), shows how slightly the law is affected for waves beyond a certain breadth:—

Depth of the Water in feet.	*Breadth of the Wave in feet.*		
	100,000	1,000,000	10,000,000
	Velocity of Wave per Hour in Miles.		
100	38·66	38·66	38·66
1,000	122·18	122·27	122·27
10,000	364·92	386·40	386·66
100,000	487·79	1,151·11	1,222·70

Observe, however, how in this table the wave 100,000 feet in breadth remains relatively insensible of a change of depth from 10,000 feet to 100,000.

Now, Professor von Hochstetter has carefully estimated the velocity of the wave which passed from Arica to the points marked (1), (3), (6), (7), (8), (10), and (11) in the illustrative map, and his results may be briefly indicated as follows:—

Rate from Arica to station	(1) . . .	284	sea-miles per hour.
,, ,, ,,	(3) . . .	417	,, ,,
,, ,, ,,	(6) . . .	362	,, ,,
,, ,, ,,	(7) . . .	358	,, ,,
,, ,, ,,	(8) . . .	360	,, ,,
,, ,, ,,	(10) . . .	316	,, ,,
,, ,, ,,	(11) . . .	319	,, ,,

It is well to observe, first of all, how well the low rate of velocity to Valdivia accords with the theory of sea-waves, for this wave travelling along the sea-coast must have passed for the most part over shallows. The voyage to the Sandwich Isles appears to have been accomplished more rapidly than any of the others. Along the line, therefore, from Arica to (3), the Pacific has its greatest depth. Towards stations (6), (7), and (8), the sea-wave sped very swiftly, and here, therefore, the water is still deep, though not so deep as along the former route. But in voyaging onwards from the neighbourhood of the Chatham Isles (8) to New Zealand and Australia, the sea-wave lost a large portion of its velocity, insomuch that the average rate for this distance scarcely exceeds that with which the wave passed to Valdivia.

From these results it would be easy to calculate the mean depth of the ocean along the various tracks pursued by the wave-fronts. It will be found by those who care thus to apply Professor Airy's results, that the following estimates by Professor Hochstetter are approximately correct.

He makes the mean depth—

	Fathoms.
Between Arica and Valdivia (1)	1,190
,, ,, the Sandwich Isles (3)	2,565
,, ,, Opara (6)	1,933
,, ,, the Chatham Isles (8)	1,912
,, ,, Lyttelton (10)	1,473
,, ,, Newcastle (Aust.) (11)	1,501

These results are the more valuable, because the Pacific Ocean has not been so carefully sounded as the Atlantic has. And though the progress of the tidal wave has long afforded similar evidence, yet a certain amount of doubt necessarily rests over conclusions drawn from the progress of a wave which is acted upon throughout its voyage across the Pacific by the attractions which gave it birth.

We may add, in conclusion, that on December 23, 1854, a wave traversed the Pacific from Japan to San Francisco and Diego, or from (4) to the neighbourhood of (2), whose progress, dealt with according to Professor Airy's numbers, showed the mean depth of the sea between Japan and San Francisco to be 2,149 fathoms, and between Japan and Diego 2,034 fathoms. These results agree fairly with those which have been deduced by Professor von Hochstetter.

R. A. PROCTOR

A NEW FORM FOR SCHOOLS

AT the first blush this may seem a trivial subject, but when we consider the immense floating multitude of children who frequent schools, spending at least some 6,000 hours on forms during the time that they are at school, and that their health may be injuriously affected by the use of unsuitable ones, the importance of the subject becomes evident.

Dr. E. H. Schildbach states, in the *Gartenlaube*, that amongst more than a thousand children whom he examined in several schools at Leipsic, he found only a few who did not show some lateral curvature or deviation of the spinal column, traceable to the use of improper forms.

The chief defect in the construction of these forms was the great space between the seat and the table. Seats without backs soon tire out even robust children; they cannot sit upright for several hours together, and after much shifting from side to side, they are constrained to obtain relief by sitting on the very edge of the bench, and resting their arms on the table before them. The position into which they are thus forced is anything but a salutary one. The back is curved, especially in its lower half; the thorax sinks between the shoulders, and chest and stomach suffer a not inconsiderable pressure. To write in this position, one shoulder is raised much higher than the other, and the whole body is twisted unnaturally. With young and growing people the assumption of constrained positions, even for a few hours day by day, soon becomes habitual, and in many cases may lead to real deformity.

Our illustration represents the model form recommended by Dr. Schildbach, invented by Mr. E. Kunze, of Chemnitz, in Saxony, and will scarcely require a detailed description. It will be seen that the table forms an inclined plane without the usual level projection at its upper part. It is divided by cross bars into separate desks, and the boards which form the desks are movable and can be drawn out. A metal button with a lateral motion holds each board in its place, and also fixes it when drawn out. At the top in front are places for inkstands and writing materials, covered by the board when pushed home. Each seat has its separate back, of a shape best calculated to give proper support with the least possible pressure, while it allows the pupil to leave his place by stepping back over the seat without disturbing his neighbour. Underneath the table is a shelf for books, slates, &c., and beneath this there is a foot-board, an important provision against cold. The inexpensive character of this form and simplicity of its construction will be apparent to everyone.

THE NOVEMBER SHOOTING-STARS

THE earth is rapidly nearing the band of cosmical bodies to which the November star-showers owe their occurrence. Whether we are to witness a display or not depends wholly on the nature of that portion of the band through which we are to pass this year. The portion which gave the great display of 1866 has now passed many millions of miles away on its course towards the orbit of the distant planet Uranus. Nearer to us, but still many millions of miles away, is the part which we traversed in 1867, when (in America) there was a short but brilliant display of meteors, which would have afforded a yet more striking exhibition but for the full moon which dimmed their splendour. In 1868 meteors were seen in every part of the earth, and even, in America, on two successive nights. It is clear, therefore, that the portion of the band then traversed was very much wider than the part through which the earth had passed in the two former years. But even the part traversed in 1868 is more than five hundred millions of miles away from us now; and it is difficult indeed to say what may be the character of the portion we are approaching. Most probably it is even wider than the part we passed through in 1868; in which case we are sure (if the weather be but fine) to see a display of the November shooting-stars, though the same process of wide-spreading would of course tend to make the display so much the less brilliant.

It must be remembered that it will be absolutely useless to look for the meteors much before midnight of November 12—13 and of November 13—14. England does not come round to the exposed hemisphere of the earth—that is, to the hemisphere which is bearing directly through the meteor-band—much before ten o'clock in the evening; and she does not turn her full face, so to speak, towards the meteors before midnight. From that time until ten in the morning the rain of meteors is directed upon England without intermission, though no sign of the falling stars can be noticed after sunrise.

Our neighbours across the Channel propose to send observers to the shores of the Mediterranean, there to watch the meteors under more favourable circumstances than in more northern latitudes. Although we already know the principal conditions under which the meteors move, yet all observations directed to the determination of the size, colour, and constitution of these interesting bodies, will be well worth the making. The comet-nucleus of the system has now travelled nearly a thousand millions of miles away since in 1866 he passed his perihelion; and it will be interesting to learn whether the character of his train of followers is at all dependent on their distance from him.

R. A. PROCTOR

[To this note we add the following extract of a letter from Mr. Hind, which appeared in the *Times* of Tuesday.—ED.]

"The elements of the orbit in which the November meteors revolve are as follow, according to the last calculations of the Italian astronomer Schiaparelli, founded upon the accurate data obtained during the grand display in 1866. Heliocentric longitude of perihelion or of the point nearest to the sun, 56° 26′; crosses the plane of the earth's path from north to south in 51° 28′; inclination of orbit to the plane of the earth's path, 17° 45′; eccentricity of orbit, 0·9046; distance from sun in perihelion, 0·9873 (the earth's mean distance being taken as unity); semi-axis major of the orbit, 10·340, similarly expressed; period of revolution, 35·25 years; motion retrograde or opposite to that of the earth. At its nearest approach to the sun the orbit is therefore situate close to the earth's, while in aphelion it is not far distant from that of Uranus. It is well known that these numbers are almost identical with those applying to the orbit of the first comet of 1866, and I have lately ascertained beyond reasonable doubt that the comet of 1366, which became visible three days after the memorable meteoric exhibition in October of that year, when 'there was a movement of the stars such as men never before saw or heard of,' and 'those who saw it were filled with such great fear and dismay that they were astounded, imagining they were struck dead, and that the end of the world had come,' as the exaggerated language of the time has it, also moved in a similar orbit. It was, doubtless, visible during the shower on the confines of Ursa Major and Leo Minor, but the Chinese did not perceive it till three nights later. It was not seen in Europe."

PENNY SCIENCE CLASSES

IN opening the session of the Birmingham and Midland Institute recently, the President, Mr. Charles Dickens, referred to the "penny system" of instruction as "one of the most remarkable schemes ever devised for the educational behoof of the artizan;" and as this system, so far as we know, is adopted only at the Birmingham institution, we have made inquiries respecting its working there. We learn that, soon after the opening of the Science Classes in 1854, the teacher, Mr. Williams, observing that after a few terms the attendance fell off, suggested the establishment of Penny Lectures, as introductory to systematic scientific instruction. This plan answering well, an arithmetic class was commenced by Mr. Rickard, to which students were admitted on payment of one penny at the door. Subsequently other classes were started on the penny system, and now among others even chemistry and physical geography are taught in penny lessons. The chemistry class was formerly conducted on the quarterly plan, the fee being 3*s.* per term of twelve lessons. Though the fee was low, the attendance seldom reached more than 40 or 50 per night; while since the introduction of the penny system it is about 100 during the winter months. The persons attending the class are of all grades of society; but since the change to the penny system the proportion of artizans has much increased. We are not surprised at this, in fact it is what we should expect. The wage-paid class receive their earnings weekly, they pay their rent weekly, their "settlings" are made weekly, and their books they take in in weekly numbers. It is not to be surprised at, then, that a science class in which the fee is paid weekly should be popular with artizans. Where the fee is so low as one penny we do not see how a class can pay; but such institutions as that of Birmingham are not intended, and never were intended, to pay in a commercial sense. The promoters and subscribers are only too pleased to find their efforts successful in inducing attendance at the classes. Viewed in this way we believe the penny system to be the best of any; and the Birmingham and Midland Institute deserves all honour for having introduced it.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents.*]

Scientific Education at Cambridge

I NOTICE a paragraph at page 26 of NATURE, in which, while the facts are correct, a wrong inference is drawn from them. Two gentlemen at Cambridge have been appointed to lecture on subjects in natural science, and one of these has been appointed to lecture on electricity, magnetism, and botany. These facts are correct, and your informant congratulates the University on the increased desire for instruction in these subjects manifested among the members of the University, but says, "is the number of men in the University competent to teach them so small, that it has been found necessary to entrust electricity and botany to the same lecturer?" But the real state of the case is, that in the University there is not a want of those able to teach Natural Science, but a want of those desiring to learn it. In fact, there are so few who want to learn these matters of science, that we cannot afford to pay, and have no need to appoint, more than one man to do the work. The lectures which we have in these subjects are insufficiently attended. The University is not behind the age in the power of teaching these matters, but before the age. If there had been many people coming here desiring to be taught certain subjects, and we had been unable to supply that teaching, we should in that have been behind the age. But we are offering teaching which those to whom we offer it have not yet learned, or do not yet care, to appreciate. I am not saying that we have the power of showing all the wonders that the astronomers of the present day can watch with their spectroscopes. We are not well supplied with apparatus; but our want of it does not arise so much from the inefficiency of our teachers as from the apathy of those who are taught. We have quantities of excellent apparatus exhibited and lectured about daily by several of our professors well able to deal with these matters, and yet these lectures are taken advantage of by only a very few. If these lecture-rooms were once crowded, the University would only be too happy, and would immediately have at its command abundant means to increase the staff of competent teachers. We have in fine more than a sufficient number of people who can teach, and, what is more, are willing to teach, natural science, if only there are those who care to be taught.

But it would seem as if the classes, from whom the University is recruited, were behind the age in their desire to be taught these matters; for if we turn away from the University we find a very different state of things. There can be no doubt that throughout England there is a great demand for scientific education. This demand exists more or less among all classes, and it exists among the working-men of this country to an extent which could hardly be believed by those who have not had some experience in the matter. Among these there is a great desire for scientific instruction, and there is no one to supply it.

The case of the University is exactly reversed. There are 1,500 undergraduates at Cambridge, and there are more men able to teach them science than there is any need for. But look to the non-university classes of England; there are a thousand times that number eager to learn, and not all the men who come forward to teach them unite the qualifications of willingness and of competency. That there is a great demand for scientific education, and that not of a desultory kind, among vast numbers of the various uneducated classes of England, is a most certain fact. If anyone doubts this, let him go to some of our great workshops, and let him give a series of careful lectures on some scientific subject, and I will venture to say he will be simply astonished at the numbers who will come. I have seen crowding to a weekly lecture on Astronomy, or on Light, hundreds of workmen who had all been working for at least ten hours that day, and who are so greedy for instruction that on a summer evening, instead of playing at some game during their only hours of leisure, they will spend one part of it in reading, and the other part in listening to a lecturer, the intricacies of whose demonstrations require the most unhalting attention. Suppose I were to start a lecture on some scientific subject at Cambridge, probably none, or at most a score, would come. I am not setting this down to their blame, for the truth is that they have not the same need, for they have many men able to teach them anything they could possibly want to learn. I am not here stating the reasons why there should be so small a demand for scientific teaching at the University; the reasons are various and complicated, although we have not to go far to seek them; but the fact is certain. Now all this ought not to be so. There is a supply without a demand, and a demand without a supply; and the matter calls for the gravest consideration of those scientific men who care that the benefits which are to be got from the true study of science should be diffused among the people of this country. Of all things in the world, this is a demand which, wherever it exists, it is right to foster and encourage, and it can only be successfully fostered and encouraged by men whose intimate acquaintance with the subjects with which they deal renders them competent for a task at once of such magnitude and of such importance. It is not any want of teachers at the University, but the almost absolute want of teaching and teachers for those classes that presses upon us.

JAMES STUART

Trinity College, Cambridge, Nov. 8

Fertilisation of Winter-flowering Plants

MR. DARWIN has done me the honour of calling my attention to one or two points in my paper, published in your last number, "On the Fertilisation of Winter-flowering Plants." He thinks there must be some error in my including *Vinca major* among the plants of which the pollen is discharged in the bud, as he "knows from experiment that some species of *Vinca* absolutely require insect aid for fertilisation." On referring to my notes, I find them perfectly clear with respect to the time at which the pollen is discharged. My observation, however, so far agrees with Mr. Darwin's, that I find no record of any fruit being produced in January; it was, in fact, the absence of capsules on the *Vinca* which induced me to qualify the sentence on this subject, and to say "in *nearly all* these cases, abundance of fully formed seed-bearing capsules were observed." It is worthy of remark, that the *Vinca* is the only species in my list of apparently bud-fertilised plants not indigenous to this country. The second point relates to the white dead-nettle, with respect to which Mr. Darwin says, "I covered up *Lamium al um* early in June, and the plants produced no seed, although s irrounding plants produced plenty." This again would agree with my conjecture that it is only the flowers produced in winter that are self-fertilised. I may, however, be permitted to suggest that the test of covering up a plant with a bell-glass is not conclusive on the point of cross-fertilisation, as it is quite probable that with plants that are ordinarily self-fertilised, the mere fact of a complete stoppage of a free circulation of air may prevent the impregnation taking place. Has the experiment ever been tried with grasses, which, according to the French observer, M. Bidard are necessarily self-fertilised?

ALFRED W. BENNETT

3, Park Village East, Nov. 8, 1869

A Meteor

THIS evening, at 6.50, Greenwich time, I was called to my door by the letter-carrier, who pointed out a serpentine band in the sky, having a brightness rather above that of the Milky Way. It was about 3° in greatest breadth, and 20° in length. Its longest axis was in the line from the north-west point of the horizon to the pole star, from which, where nearest, it was about 20° distant. Its other extremity was very near the Milky Way, and surpassed every other part in brightness. Its pole-ward termination was faint, filmy, and bifurcated.

The postman said, "About five minutes ago," *i.e.* 6.45 p.m., "whilst waiting at another house, I suddenly became aware of a great light, but on looking up, instead of a shooting star, as I expected, I saw a fixed crooked line, as broad as my finger, and quite as bright as that star" (pointing to Jupiter). It gradually became broader and fainter, but not longer; and I came on here as fast as I could to let you know about it."

I observed it at intervals of five minutes; and observed that it gradually grew fainter and straighter, and moved slowly towards the north-east, its axis remaining apparently parallel to itself throughout. I saw it distinctly at 7.35, but was not satisfied that I did so at 7.40. It must have remained visible from 50 to 55 minutes.

W. PENGELLY

Lamorna, Torquay, Nov. 6, 1869

[It is to be hoped that advantage was taken of this almost unprecedented opportunity to bring the spectroscope to bear upon a meteor cloud. From other accounts the meteor itself appears to have been exceptionally brilliant, and to have burst with noise, as of a rocket (Falmouth); to have changed its colour from yellowish red and lurid red to brilliant green at the moment of explosion, and then from violet to orange (Birmingham.) Another account (Wimborne) states, that at the moment of explosion the colour was dazzling purple and blueish, fading into white at its upper extremity. The cloud was observed to assume a serpentine form both at Bristol and Stokesay. Mr. Pengelly's 50 or 55 minutes' duration was most nearly equalled at the latter place, where it was observed for half an hour. There are ample elements for the determination of the meteor's path.—ED.]

Tempel's Comet

I ENCLOSE an orbit for the comet discovered by Tempel on October 11, of which no elements have yet been published in the *Astronomische Nachrichten*. Indeed, but for an observation kindly sent me by Dr. Winnecke, and not yet printed, it would not have been practicable to work out an orbit.

Elements of the Orbit of Tempel's Comet, 1869, *Oct.* 11.

Elements calculated from an observation at Bonn, Oct. 12, one by Dr. Winnecke, at Carlsruhe, Oct. 17, and a third at Leipzig, Oct. 23:—

Perihelion Passage, 1869, Oct.	8·4421	Greenwich M. T.
Longitude of Perihelion . .	124° 41′ 1″	From appt. Equinox.
,, Ascending Node	311° 24′ 4″	From appt. Equinox.
Inclination to Ecliptic . . .	68° 48′ 8″	
Log. perihelion distance . .	0° 08995	
Heliocentric Motion Retrograde.		

The above orbit does not resemble that of any comet previously computed.

J. R. HIND

Observatory, Twickenham, Nov. 8.

NOTES

THE argument that British manufacturing and commercial superiority cannot be maintained unless the means of a sound scientific education be placed within the reach of all classes all over the kingdom, seems likely to be put to the proof. Oxford and Cambridge local examinations, the examinations by the Society of Arts and the South Kensington Museum, we are told, only serve to show how backward we are in real knowledge, and that we want more schools, more places of instruction. Well, by act of parliament, a number of our Public Schools are to be ruled by new "Governing Bodies," the members of which are to be appointed by different authorities; but we confine ourselves here to the fact that among those authorities are "the President and Council of the Royal Society." These gentlemen, the very head and front of British science, are to nominate a member of the "Governing Body" of each of seven schools, namely, Westminster, Eton, Winchester, Harrow, Charterhouse, Rugby, and Shrewsbury. Here is, indeed, an innovation! The President and Council of the Royal Society will of course nominate men of science. Consequently, science will be taught in all those schools, side by side with the classics. Can the two run together? If science goes up, will Greek and Latin and scholarship go down? We hope not; but these are questions for the future to answer. Meanwhile, we have much pleasure in stating that the two nominations already made by the Council of the Royal Society are such as will command universal approval. Prof. G. G. Stokes, Secretary of the Royal Society and President of the British Association, has been nominated for Eton School, and Mr. W. Spottiswoode, F.R.S., for Westminster School. The interests of science could not be in better hands than these, and we can only hope that the five nominations yet to be made will be equally acceptable. There is movement too in other quarters. The University of Durham is stirring, and desires to establish a school of Physical Science, and to change its humdrum terms of twenty-four weeks in the year, for terms of eight months. All hail to the innovation! Theology at Durham will now have Science for a companion. And the great county of York does not mean to be left behind, for a preliminary meeting of the general council of the Yorkshire Board of Education has been held at Leeds, to talk about the establishment of a Science college. Should this come to pass, the youth of the North of England will have a fair opportunity for scientific education, for Lancashire is already provided with a college at Manchester.

WE learn from the *Astronomical Register* that an Observatory of the first order has been recently inaugurated at Florence with much solemnity, and in the presence of a large number of scientific men of all countries: among them being many astronomers who had come to Florence to discuss the measurement of the great European arc. From the municipality of Florence, the provincial council, the Government, and the King himself, have come the necessary funds : Professor Donati stating that in Italy, at all events, the maxim is well understood that "as private means are insufficient for continuous scientific researches, and as it is clear, that every advance of science, whatever it may be, becomes sooner or later of the greatest public benefit to all classes; it is therefore natural and just that the public coffers, and those of the wealthy, should unite to enrich the patrimony of science, which is the patrimony of all." What a happy day it will be for England when her administrators and statesmen, and Cabinet Ministers, come up to the Italian standard, when the governing classes are sufficiently educated, and single-minded, and far-sighted, to help in the erection of scientific workshops. A crying want at the present moment is a Physical Observatory. He would be a brave man who would suggest that the municipality of London and the Government should supply us with one!

HERE is a welcome piece of news from the *London Gazette* :—"The Queen has been graciously pleased to give orders for the appointment of Joseph Dalton Hooker, Esq., M.D., Director of the Royal Botanical Gardens at Kew, to be an Ordinary Member of the Civil Division of the Third Class, or Companions of the Most Honourable Order of the Bath."

THE Geographical Society commenced work on Monday evening, the *pièce de résistance* being a long communication from Dr. Livingstone, full of interest and important details, to which we may return; the main drift of it is already known to our readers.

MELBOURNE no longer enjoys a monopoly of Australian science. A "Royal Society of New South Wales," to which we heartily wish success, has been established in Sydney, and the first volume of its "Transactions" is now before us. This publication—an octavo of about ninety pages—may be accepted as an earnest of good work yet to come; for, besides the inaugural address by the President (Rev. W. B. Clarke) it contains mathematical, geological, astronomical, and statistical papers. Chief Justice Cockle, F.R.S. (who, by the way, is President of a Philosophical Society in Queensland), contributes a paper on Non-linear Coresolvents; Mr. Gerard Krefft one on the Bones found in a Cave at Glenorchy, Tasmania; Mr. Smalley, the Government astronomer, one on the Mutual Influence of Clock Pendulums; and Prof. Pell one on the Rates of Mortality and Expectation of Life in New South Wales, as compared with England and other countries. In all, there are seven papers in the volume, and we congratulate our cousins at the antipodes on their meritorious contributions to the cause of science.

ON Saturday last the Cambridge Philosophical Society celebrated their jubilee by a dinner, Professor Cayley occupying the chair. It was pleasant to hear the venerable Professor Sedgwick give an account of the formation of the Society, and bless God that he had lived to see it so far on its way.

FROM Saint John's College, Cambridge, we learn that besides seven minor scholarships or exhibitions, there will be offered for competition an exhibition of 50*l*. per annum for proficiency in Natural Science, the exhibition to be tenable for three years in case the exhibitioner have passed within two years the previous examination as required for candidates for honours; otherwise the exhibition to cease at the end of two years. The candidates for the Natural Science exhibition will have a special examination on Friday and Saturday the 29th and 30th of April, 1870, in chemistry, including practical work in the laboratory, physics (electricity, heat, light), and physiology. They will also have the opportunity of being examined in one or more of the following subjects, geology, anatomy, botany, provided that they give notice of the subjects in which they wish to be examined four weeks prior to the examination. No candidate will be examined in more than three of these six subjects, whereof one at least must be chosen from the former group. It is the wish of the master and seniors that excellence in some single department should be specially regarded by the candidates. They may also, if they think fit, offer themselves for examination in any of the classical or mathematical subjects. The exhibitions are not limited in respect to the age of candidates.

WE are promised a new illustrated weekly—the *Graphic*—shortly, and we observe with pleasure that Science is to find a place in it.

THE attention of the Ethnological Society during their last session was directed (in a series of able papers recorded in their journal) to the Megalithic remains—cromlechs, dolmens, stone circles, &c., such as are found in our own island, as well as in all parts of Southern Europe, in India, Arabia, and in Africa along the shores of the Mediterranean. The desirability of collecting evidence of at least relation of race in their builders, which the identity of form and size of these stone wonders suggest, whether found in Kaseem, in Arabia, or in Avebury in Somersetshire—induced the assistant-secretary of the Society to send a competent photographer to take views of the stone circles of Wiltshire. In these views, 12 inches by 10, by a simple method of scale measurement, the exact dimensions are recorded, and the compass bearings noted; enabling the closet student to make careful comparisons. Will not our learned societies, and munificent individuals interested in prehistoric studies, come forward to provide funds to secure a systematic delineation of at least the European Megalithic structures?

WELL-CONSTRUCTED maps are among the most needful appliances of scientific education: we are glad to notice a Physical Map of India, compiled by the Librarian R.G.S. of a size sufficient to render it easy of use, yet showing distinctly the comparative mountain elevations, the great alluvial plains, river systems, &c. This map, which has been adopted by one of our greatest educational establishments, is, we understand, the first of a series.

AT the last meeting of the German Chemical Society in Berlin, the President, Prof. Hofmann, opened the proceedings by referring to the great loss the Society had sustained through the death of their honorary member, Thomas Graham; and remarked: "Graham's was one of those singular minds which create an open new roads of science. Our young society deems itself fortunate to see his name inscribed amongst its members. Let us honour his memory by rising from our seats." On the 9th of October, a German chemist of high standing followed Graham into the grave. Otto Luinė Erdmann was born in Dresden, in

1804. He began his career as a pharmaceutical chemist, but soon embraced pure science with such success that a chair of Chemistry was given to him in the University of Leipzig, in 1830. This chair he occupied until his death; attending to his professional duties with great zeal, although a number of practical occupations (that of director of the Leipzig and Dresden Railway Company, the Leipzig Gas Company, &c.) divided his attention. We owe to him a great number of mineral analyses, a celebrated investigation of indigo, from which he was the first to obtain isatine (in 1840), and several other derivatives, also the analyses of several colouring matters, as jaune indien, euxanthic acid, oxypicric acid, of stearic and of mellitic acid. Together with Marchand he determined a great number of atomic weights with considerable accuracy. With the same chemist, and, after his death, with Professor Werther in Königsburg, he edited the Journal "für practische Chemie"—a journal which will most likely cease to appear, both editors, as well as the publisher, having died during the last few months.

THE Königsburg chair has been offered to Prof. Baryen in Berlin, who declined it, and it still remains open.

PROFESSOR STRECKER of Tubingen has accepted the chair of Chemistry in Wurzburg, in place of the late Professor Schirer, who was known chiefly as a physiological chemist.

IN the Annual Report of the Gardens of the Royal Botanic Society, Regent's Park, recently issued, it is stated that during last season free orders of admission to the gardens for the purpose of study have been granted to 200 students and artists, and 10,653 specimens of plants have been given to professors and lecturers at the principal hospitals and schools of art and medicine. The collection of living economic plants now contains specimens of all the spices and condiments in domestic use, most of the tropical esculent fruits, and many of those from which furniture and other woods are obtained, the principal gums and medicinal products, and the poison-trees of Brazil and Madagascar. The lecturers at the schools of medicine attached to the various metropolitan hospitals are greatly indebted to the liberality of the Botanic Gardens in furnishing them with a copious supply of fresh specimens, so difficult to obtain in London, and without which the lectures would lose so much of their instruction. We may suggest, however, whether some improvements might not be introduced into the so-called "herbaceous" department of the Gardens. A needless amount of space appears to be occupied by the arrangement of British plants in two different classifications, the Natural and the Linnæan, the latter being now entirely abandoned by all teachers of botany. Sufficient care also is not taken that the labels should correspond to the plants really growing beside them. It is confusing to the student to find immediately in front of a label a plant growing in full luxuriance belonging to an entirely different family, which has accidentally strayed there, and has not been weeded out. At Kew this department is kept in much better order. The Royal Botanic Society are now soliciting contributions in aid of the extension of their magnificent winter-garden.

SCIENTIFIC readers who want a treat should read M. Leverrier's masterly argument against M. Chasles in his assertion, based on the forged papers, that Pascal had anticipated Newton's discoveries. How any one could pretend to be unconvinced after such an overwhelmingly true and logical exposition of facts surpasses comprehension. Under the title "Examen de la discussion soulevée au sein de l'Académie des Sciences au sujet de la découverte de l'attraction universelle" M. Leverrier has republished from the *Comptes Rendus* the whole of his argument in ninety-two quarto pages. We recommend all who can to read it.

THERE was an omission—which we are very glad to supply—in our last week's Note on the results of the dredging expedition of the *Porcupine*. A large, if not the greatest share of the labour, both as regards time and work, fell upon Mr. Gwyn Jeffreys, and this fact will make all look forward to the publication of the results with a greater interest.

THE many friends of Professor Morris, who have long admired the zeal displayed by him, not only in giving to the world the sound knowledge which he possesses of geology and palæontology, but in presenting it to his pupils in such a form as to enable them profitably to apply it in after life, now propose to give their recognition and appreciation a substantial form, by presenting him with a suitable testimonial. To carry out this object, a committee has been formed, and Mr. Milnes, F.G.S., of the Coal Exchange, London, has accepted the office of treasurer to the committee, of which Sir Roderick Murchison is president.

THE fruit of the Mango has recently been sold in Covent Garden market, obtained from Madeira. It had previously fruited at Chatsworth, and in the garden of Lord Powis; but, we believe, has not before been offered for sale in this country.

AMONG the books which have reached us this week are two to which we wish especially in the interim to call attention in this column. One of them is the new edition of Sir John Lubbock's "Prehistoric Times," considerably enlarged; and the other is "The World of the Sea," translated from the French of the regretted Moquin Tandon, illustrations which it does one good to see, forming one of the many points of the latter.

THE editors of the new "Journal of Ethnology," published in Berlin, circulate with their first number a hand-bill, in which, after calling attention to the extreme importanc of photography for ethnographical purposes, they request photo aphers of all nations to send to the publishers of the Journal t r addresses, and a statement of the ethnographical types to be fo nd in their neighbourhoods. It may fairly be questioned, whether scientific knowledge is likely to be much advanced by the indiscriminate collection of photographs of individuals, selected by persons totally unacquainted with ethnography. The editors seem, moreover, to be somewhat premature in issuing such a notice as this, as they appear to have taken no steps to arrange for the photographs being published; neither do they undertake to deposit them in any public library or museum. They merely say that men of business will no doubt be found, who will assist in a matter which assures them, as well as the photographers, the renumeration to which they are entitled. We venture to express a hope, that if any general response is made to this notice, the photographers will be at least cautioned to use great care in ascertaining the tribe and parentage of the subjects they select; also that, in all cases, one photograph may be taken i exact profile and another in exact full face.

ASTRONOMY

Winnecke's Comet

THE following ephemeris of Winnecke's comet been calculated by M. Oppolzer.

	R.A. h m s	N. Decl. ° ′
Nov. 11	1 25 40	11 30·0
13	1 24 25	11 12·8

CHEMISTRY

New Test for Alcohol

LIEBEN has discovered a new and very delicate test for the presence of alcohol, depending upon its conversion into iodoform. The liquid under examination is heated in a test-tube, into which are then introduced a few grains of iodine, and a few drops of potash-solution; whereupon, if alcohol is present, a yellow crystalline precipitate of iodoform is produced immediately or after some time, according to the degree of dilution of the liquid. This test is said to be capable of detecting 1 part of alcohol in 12,000 parts of water. For greater certainty, it is best to examine the precipitate with the microscope, iodoform exhibiting the appearance of hexagonal plates or six-rayed stars.

The test just described is capable of an important physiological application. It is generally supposed that alcohol introduced into the animal organism in the form of wine or other spirituous liquors becomes completely oxidised, and does not pass into the urine as alcohol, but in the form of some product of transformation. Lieben, however, by applying the new test to the urine of a man who had drunk a bottle of wine half an hour before, was able to detect the presence of alcohol in it. A second portion of urine voided by the same individual, an hour later, and a third, after another half-hour, still exhibited the peculiar reaction under consideration. The urine was of course distilled before applying the test, and it had been previously ascertained that none of the other volatile matters contained in it would produce a similar reaction.—[Ann. di Chim. app. alla Med., Sept. 1869, p. 136.]

Preparation of Silver Nitrate

P. SCIVOLETTO proposes the following modification of the process of preparing silver nitrate for use in medicine, photography, &c. This salt is usually prepared from old silver containing copper, by dissolving the alloy in nitric acid, evaporating to dryness, and calcining the residue as long as nitrous fumes continue to escape. The product is a mixture of silver nitrate and cupric oxide, from which the former may be dissolved out by water. The inconveniences of this process are the time it takes, and the difficulty of ascertaining when the cupric nitrate is completely decomposed. To obviate these inconveniences, the author, after evaporating the solution of the mixed nitrates to dryness, redissolves them in water, and precipitates the silver from the neutral solution by means of a clean spiral of copper foil. The precipitated silver is then redissolved in nitric acid, and the resulting nitrate is either crystallised, fused, or left in solution, according to the use to which it is to be applied.—[Ann. di Chim. app. alla Med., August 1869, p. 70.]

A. SAYTZEFF has discovered a new method of converting fatty acids into the corresponding alcohols, namely, by the action of dry sodium amalgam on a mixture of a fatty acid with the corresponding chloride; e.g. acetic acid and acetyl chloride yield ethyl alcohol. In this manner he has prepared ethyl, propyl, and butyl alcohol.—[Zeitschr. f. Chem. (2), v. 551.]

GRUNE has found that the photographic image, as ordinarily produced, is on the surface, and not in the substance of the collodion film. By transferring the film to wood, and then dissolving out the collodion by means of ether, a purely metallic image is left, admirably suited for the purposes of the engraver.

PHYSICS

Thalen's New Map of the Spectra of the Metals

M. ROBERT THALÉN has contributed to the Royal Society of Upsala an important memoir on the determination of the wave-lengths of the metallic lines of the spectrum. Dissatisfied with the pure results of refraction, as not being sufficiently refined to meet the requirements even of ordinary analytical accuracy, the author resolved to construct a new chart, based on the principle of wave-lengths. For the systematic examination of spectra, an electric source of light should always be employed, and entire groups of characteristic lines ought to be observed in all cases. The ordinary spectroscope, with a fine micrometer scale, gives readings which vary sensibly with the temperature and material of the refractive medium; and two such instruments cannot be compared with each other unless by specific tables, or graphically. Accordingly, the highest accuracy can only be attained by direct comparison with the dark lines of the solar spectrum, which themselves furnish an excellent micrometric scale. M. Thalén has therefore founded his experiments on the laborious achievement of Ångström, with whose "normal solar spectrum" he was early associated.

The actual course of operations was as follows. Each bright metallic ray, whose spectrum it was desired to study, was laid down on the plates given by Kirchhoff and Hoffmann (A to G) or by Ångström and Thalén (G to H); these rays were next referred to Ångström's plates of the normal spectrum of the sun, unless a direct comparison with the solar lines could be made; and, lastly, the rays were drawn in the order of their wave-lengths as thus obtained, and sometimes with the assistance of a graphic method, on a map which accompanies the memoir.

The instruments employed in this research consisted of a large Ruhmkorff induction coil, aided by a sufficiently powerful condenser; and a voltaic battery of fifty pairs furnished the light for certain determinations. The spectroscope consisted of two tolerably large telescopes (one being used as a collimator) and a carbon disulphide prism of 60°. In favourable cases, two such prisms or six flint-glass prisms of 60° were employed; but when the intensity was very feeble, only one (of the latter kind) could be used.

The registration in the solar spectrum of the lines of incandescent bodies may be effected by different methods. When the voltaic arc is operated with, or even the induction spark (provided, in this case, that the electrode is made of the metal submitted to experiment), it is convenient to bring the rays from the two sources of light into the slit of the collimator in such a manner that the solar and metallic spectrum are one above the other. If the lines of the latter have sufficient intensity, the reference is effected without difficulty. On the other hand, when the intensity of the electric spectrum is feeble—which is generally the case when the spark is taken between electrodes moistened with saline solutions—it is better that the two pencils should enter the slit in the same direction, so as to be mutually superposed. As the bright lines are now scarcely visible on the illuminated background of the solar spectrum, the latter must be temporarily excluded by a screen; the vertical wire in the eye-piece of the telescope is made to coincide exactly with a bright metallic line; and then, on re-introducing sunlight, its position among the dark lines is seen with precision. It is not unworthy of notice that the exactness of this observation is impaired by a somewhat singular circumstance. If the wire and the Fraunhöfer lines are seen simultaneously in the focus of the eye-piece, the wire being placed among the weaker and narrower lines, it commonly happens that these entirely disappear, or can only be made out with difficulty. The great difference between the intensities of the two objects, and the diffraction fringes produced by the two sides of the wire, are, no doubt, the causes of this curious phenomenon.

M. Thalén gives a table in which the normal spectrum of the sun is recorded in wave-lengths, and compared with the refraction spectrum of Kirchhoff. By its aid, the metallic lines on the chart accompanying the author's paper may be identified with those of the refraction spectra alluded to, and an approximate value can be obtained of the wave-length corresponding to any line. The chart itself gives, in millimetres, the wave-lengths of metallic lines within about 0·0000001 of their true value. It was drawn by hand on paper upon which the scale had already been printed without the usual damping process; in this manner all shrinking was avoided. It is rendered still more valuable by a long appendix of tables, in which all its numerical elements are appropriately distributed among the respective metals. Only the most intense lines, such as are obtained by the induction apparatus, have as a rule, been submitted to measurement.

The following are the names of the metals whose lines coincide with those of the solar spectrum: sodium, calcium, magnesium, iron, manganese, chromium, nickel, cobalt, and *titanium*. The chart contains lines belonging to forty-five metals. Iridium, rhodium, ruthemium, tantalum, and niobium were examined, but without any definite result. The spectrum of air is given at the bottom of the chart, for the sake of reference, and some integers, roughly representing the intensity of the lines.

Some of the lines which show very strongly with metallic electrodes become very weak, when a saline solution is taken, and the more so as this is diluted. Two large and well-marked groups belonging to zinc and cadmium appear only when the metal itself forms the electrode, not the slightest trace of them appearing with a saline solution.

In a concluding note, M. Thalén points out the probable existence of titanium in the sun. Titanic oxide only gave feeble lines, of which a few characteristic individuals were mapped with difficulty. These were afterwards found in the spectrum of calcic chloride, with which some gas-carbon electrodes had been impregnated; but with electrodes of a different material the lines did not reappear. Perfectly pure titanic chloride, however, readily furnished them; and titanium was also obtained, by a chemical process, from the ash of the coal which had yielded the gas-carbon. A direct comparison of the numerous and delicate titanium lines with those of Fraunhöfer, under high dispersive power, left no doubt whatever that titanium must now be added to the list of solar metals.

PHYSIOLOGY

Gases of the Secretions

PFLUGER has investigated the gases of urine, milk, bile, and saliva. The quantity of nitrogen gas is very much alike in all, being in urine ·9, in milk ·75, in bile ·5, in saliva ·75 per cent. in volumes. The quantity of oxygen, on the contrary, varies much more, being in urine ·075, in milk ·095, in bile ·1, in saliva ·5 per cent. Pflüger attributes the larger quantity of oxygen in saliva to the fact that in the much less rapid secretions of bile, &c., the epithelium of the secreting passages consumes, during secretion, a large portion of the oxygen contained in the secreted fluid. In the more swiftly secreted saliva, the oxygen escapes in a large measure this consumption. The quantity of carbonic acid varies according to the reaction of the secretion. In alkaline, bile, and saliva, it reaches 56·1, and 64·7 per cent.; in neutral or acid urine, milk, and bile, it sinks as low as 13·7, 7·6, 5 per cent. respectively.—[Archiv. für Physiol. ii. 156.]

According to Bogoljubow, the carbonic acid of the bile depends largely on the quality and quantity of food taken. It seems to diminish during the stay of the bile in the gall bladder.—[Centralblatt f. Med. Wissen. 1869, No. 42.]

Changes in Milk

KEMMERICH brings forward observations to show that in standing milk, especially at blood-heat, an increase of the *casein* takes place at the expense of the *albumen*. He also confirms the statements of previous observers, that in milk (and cheese) the quantity of fat increases on keeping. He attributes, however, this "ripening of the cheese," to the action of fungi.—[Archiv. für Physiol. ii. 401.]

Effect of Alcohol on Animal Heat

CUNY BOUVIER affirms as the result of experiments on rabbits (apparently carefully conducted with due sense of sources of error) that alcohol lowers the temperature of the body, in small doses to a slight in large doses to a very marked degree.—[Archiv. für Physiol. ii. 370.]

Metamorphosis of Muscle

O. NASSE, extending the previous observations of MacDonnell and others, affirms that *glycogen* is a normal constituent of muscle, the quantity existing in frog's and rabbit's muscle amounting to 3—5 per cent. of the wet mass. He also states that in living quiescent muscle sugar is totally absent, or present in inappreciable quantity only. The conversion of glycogen accompanies rigor mortis, whether natural or artificial, and is also brought about by muscular contraction. Nasse further shows that muscular contraction and rigor mortis are accompanied by a consumption of the total carbo-hydrates of the muscle. The amount of sugar (or glycogen) lost under these circumstances is insufficient, however, to account for the acid (paralactic) produced at the same time; indeed the two processes run by no means parallel, and apparently are not connected.—[Archiv. für Physiol. ii. 97.]

Vertebrate Epidermis

F. E. SCHULTZE describes various modifications of the uppermost layers of the epidermis in vertebrata, distinguishing between *cuticular thickenings* of living cells and *cornification* of dead ones. In particular he describes curious laminated cuticular thickenings of the epidermic cells of various species of *hippocampus*. These cells he proposes to call *flame*-cells, from their curious resemblance to the flame of a candle.—[Max Schultze's Archiv. v. 295.]

Development of Grey Matter of Brain]

ACCORDING to Arndt, the grey matter of the convolutions of the rabbit at birth consists of nuclei imbedded in a protoplasmic matrix, studded with granules, and very faintly fibrillated. After birth the matrix becomes increasingly fibrillated, the granules partly coalesce and partly become dispersed. The nuclei become separated through a greater development of the matrix, and a nucleolus appears in them by coalescence of previously existing nucleolini. Part of this differentiated matrix is directly gathered round various nuclei to form the ganglionic cells and their branches, other parts become arranged in strands to form the axis cylinders of nerves, while the rest remains as the permanent granular faintly fibrillated matrix of the adult brain. Arndt tries to accommodate the "Cell theory" to these new facts.—[Max Schultze's Archiv. v. 317.]

Regeneration of Spinal Cord

MASIUS and VAN LAIR assert that if strong frogs be operated on in early or mid winter, complete reparation of structure with restoration of powers takes place, even when sections of the whole spinal cord 1–2 mm. in length have been removed. Degeneration occurs first at either cut surface: the central end swells by deposition of new tissue into a hollow cup-shaped bulb; the peripheral contracts into a cone fitting into the former; and so union takes place.—[Centralblatt, Med. Wissen. 1869, No. 39.]

SOCIETIES AND ACADEMIES

Syro-Egyptian Society, Nov. 2.—Mr. W. H. Black, F.S.A. in the chair. The latest communication from Dr. Livingstone, that he has found what he believed "to be the true sources of the Nile, between 10° and 12° south (latitude) or nearly the position assigned to them by Ptolemy," was received with much satisfaction; and the passages in the Greek text of Ptolemy's geography, relative to "the mountain of the moon," from which the lakes "of the Nile receive the snows," *twice placed by him in 12½ south latitude*, were read; and the old traditional maps, showing a mountain range of about 10° of longitude in extent, with streams running northward into two lakes (as published in the Amsterdam edition of 1605), were compared therewith. A resolution was then passed, sympathising with Dr. Livingstone in his laborious researches, and congratulating the present age on this confirmation of ancient scientific literature by means of modern exploration.

Mr. Black described the results of his own recent application of the symbolic and mathematic teaching of the great pyramid to the geometric geography of Africa; stating the full conformity of that monument to the geodetic laws and uses of other uninscribed megalithic monuments in Asia and Europe, which have been erroneously assigned to religious and superstitious purposes. He promised to illustrate the subject further, and to demonstrate by diagrams the results then verbally described, at a future meeting of the society.

Anthropological Society, Nov. 2.—Dr. Beigel, V.P., in the chair; the following new members were announced:—*Fellows.*—Captain G. J. D. Heath; Dr. Samuel E. Maunsell, R.A.; Messrs. Thomas Milne, M.D.; E. W. Martin; Robert Watt; Horace Swete, M.D.; Lieut. Wm. Francklyne; and Wm. Pepper. *Hon. Fellow.*—M. Le Baron d'Omalius d'Halloy. *Corresponding Member.*—Professor Dr. August Hirsch.

Mr. Pike read a paper on the Methods of Anthropological Research. He considered it useless to speak of methods of research without some previous definition of the objects of research. The real difficulty in anthropology was to know what to observe, and how to verify. He believed that the science could advance only by a double method of observation—the observation of mankind individually and in masses, and that the conclusions suggested by the observation of masses, races, or nations must be verified by the observation of individuals, and *vice versâ*. For this reason he thought it was a mistake to speak of ethnology as a science, as it consisted only of a series of disjointed observations without conclusions, and without the means of verifying conclusions if made. Mr. Pike then reviewed at considerable length the ramifications of Anthropology into anatomy, physiology, psychology, and the various subdivisions of those studies, suggesting that all kinds of unsuspected correlations were yet to be discovered by a rigorous application of a scientific method. The relations of mind to body, of faculty to faculty, of one part of the body to another, were still removed but little from the realms of mystery from which only anthropology could thoroughly drag them away. Mr. Pike concluded by describing anthropology in one of its aspects as the only kind of philanthropy which could be of service to mankind—philanthropy founded upon science.

BIRMINGHAM

Natural History and Microscopical Society, October 26.—Mr. G. Heaton exhibited a collection of sea urchins, of the species *Echinus Sphæra*, recently taken on the North-West coast of Ireland, and exceeding in dimensions the largest recorded by Professor Forbes. Mr. W. R. Hughes, in reference to these magnificent specimens, gave a general account of the structure and functions of the Echinodermata. He contrasted the mode in which calcareous matter is deposited in the Mollusca and other classes, with that which is characteristic of the Echini. Thus, in the Mollusca it is secreted in various directions by the "mantle" of the animal; in Crustacea it is deposited externally to the epidermis, and is cast off when the animal becomes too large for its covering, and replaced by a new shell reproduced in like manner; while in the tubicular Annelids a similar process prevails. In Anthozoa and Madreporidæ it is secreted at the base of the animal from its gelatinous investment; and again in Spongiadæ innumerable calcareous spiculæ are deposited throughout the mass. In Echinodermata, on the contrary, a method totally different from all the preceding is observed, the calcareous matter really forming a box, as distinguished from a shell, in which the viscera float in a surrounding medium of sea-water, and inasmuch as this box can never be cast off or replaced during the growth of the animal, from its original size of a pea, up to its full dimensions of 13 in. or 14 in. in circumference, a very special and wonderful provision is made for the gradual enlargement of the dwelling. This is effected by the secretion of the calcareous salts, not only on the interior but at the margins of the 600 pieces or plates of which the case is composed; so that by the slow extension of every one of these at its edges, the whole undergoes a corresponding gradual expansion in every direction, commensurate with the development of its tenant. Mr. Hughes referred to the fact that the magical number 5 prevails in a peculiar manner throughout the class, instancing the 5 rayed star-fish, the 5 teeth, 5 jaws, &c., of the Echini. The subject was further illustrated by various recent and fossil Echinoderms, contributed by Mr. R. M. Lloyd; spines of *Sidaris* from the South Sea Islands, the star-fishes *Cribella rosea* and *Uraster rubens*, by Mr. G. S. Tye, &c.

EDINBURGH

Geological Society, November 4.—The president, Mr. Geikie, delivered the opening address. After congratulating the society on its recent progress, he passed on to bring before its notice three special branches of inquiry, wherein much useful work remained to be accomplished. The first of these related to the study of organic remains, which, in the opinion of the speaker, was too much dissociated from that of the strata among which they are preserved. He thought that the palæontology of each geological formation should be as far as possible the natural history of a certain period of the past life of the globe. We should try to discover from the fossil remains more of the general character of the contemporaneous fauna and flora; the nature of the sea-bottom or land-surface on which they flourished; their various modes of growth; their distribution in space as well as in time; the light which they cast upon changes in the organic world, and the influence of these changes upon them; the causes of their decay as individuals and as species, and the circumstances under which they had been finally entombed. Mr. Geikie illustrated this subject from the rocks of the central valley of Scotland. He then passed on to the second topic, which related to the mineral structure of rocks or petrography. That branch of the science had fallen into strange neglect in this country. After indicating what had been done and what was now doing in Germany in that department, he pointed out the special way in which it lay open to observers in Scotland, and pressed upon the society the desirability of cultivating it. The third branch of his address bore on the balance of the various forces which have been instrumental in modifying the surface of the earth. Observers in Britain, he said, enjoyed special advantages when they set themselves to investigate this question. The completeness of their geological series, the diversities of configuration in their country, the extent of their coast line, the multiplicity and variety of their brooks and rivers, all conspired to aid them. On the other hand, they were apt from this very completeness of their opportunities to take a local and limited view of the phenomena. This he thought had really happened in the case of their estimate of the potency of the sea as a geological agent. Their position as islanders had led them to take an exaggerated view of the results attributable to the waves in the general economy of nature, and to undervalue the power of rains, springs, frosts, and rivers, which in this country do not produce the changes which they effect elsewhere. He pointed out how vast was the extent of coast-line where the sea did not reach the solid framework of the land, but was barred back by long lines of alluvial deposit—the waste of the land brought down by the streams. The sea in these instances, although perpetually wasting the sand-bars, did not perceptibly encroach on the land, for the bars were constantly being renewed from behind. The land, though not diminishing in breadth, was inch by inch sinking in height, the power of the sea being no more than equal to sweeping away the detritus brought down to the coast by the drainage from the interior. Although seemingly paradoxical, he yet believed that in the general balance of forces the influence of the ocean is more conservative than destructive, there being a greater area of rock under the sea, preserved there from that universal corrosion and removal which befall every part of the earth's crust that rises above the waves. The concluding portion of the address dealt with the relation at present subsisting between science and religion.

BERLIN

Chemical Society, October 25.—Prof. Fritzsche communicated a paper on the action of cold on tin. Tin was exposed to 40° C., the temperature produced by Carré's refrigerator. It was found changed in colour and structure, the latter becoming granular, and the colour turning from white to grey. By heating it to less than 100°, the white colour could be restored. By prolonging the action of the cold, the tin became so brittle, that it could easily be powdered, and a kind of blister appeared on the surface of the metal. This explains similar changes observed by the same chemist in block-tin and organ pipes exposed to the cold of a Russian winter. Emmerling reported on liquefied oxychloride of carbon. It constitutes a colourless liquid, and boils at 8° above zero. The oxychloride of carbon prepared in the usual way contained an excess of chlorine, which was absorbed by passing it over antimony, before the gas was condensed through cold. Der Müller communicated some observations on the preparation of Chloral. Prof. Kekulé sent in a report on Chemistry at the German Association of Innsbruck. This report being not as yet complete, we shall return to the subject.—A. O.

PARIS

Academy of Sciences, November 2.—MM. Sainte-Claire Deville and Dieudonné communicated a paper on the industrial employment of the mineral oils for heating engines, especially locomotive engines, in which they describe certain experiments made by the company of the Chemins de Fer de l'Est, tending to show that petroleum and coal oils may be advantageously employed to heat the boilers of locomotives. M. P. Thenard read a note in reply to that communicated to the Academy at its last meeting, by M. Pasteur, on the employment of heat for the preservation of wines. M. de Verneuil made some remarks on the conclusion of M. de Tchikatcheff's work on Asia Minor, giving a general account of the contents of the volume, which treats of the physical geography and natural history of that region. A memoir was presented by M. Hébert, entitled "Researches on the Chalk of the North of Europe." He distinguishes in the chalk of the Paris basin some distinct stages, the distribution of which, especially in the north of Europe, he indicates. A paper, by MM. Fougué and Gorceix, containing a chemical investigation of several of the gases with combustible elements of Central Italy, was presented by M. C. Sainte-Claire Deville. The authors have analysed 28 gases, collected in Italy—4 from the Tuscan *lagoni*, 24 from various stations in the Apennines, between Modena and Imola. Their analyses of the former confirm the results of MM. C. Sainte-Claire Deville and Leblanc: they contain free hydrogen. None of the gases contain acetylene, hydrocarbons of the series $C^{2n}H^{2n}$, or oxide of carbon. The gas from Sassuno contains hydride of æthyle, and those from Porretta carbonic acid in considerable quantity, and traces of sulphuretted hydrogen. These gases are characterised by the predominance of marsh gas in their composition, and they are very frequently impregnated with vapours of liquid hydrocarbons of the series $C^{2n}H^{2n+2}$. M. Faivre communicated an account of experiments upon the effects of wounds of the bark by annular incisions under various physiological conditions. In a note upon a measure of length unalterable by changes of temperature, M. H. Soleil proposes to make standard rules of beryl. He remarks that beryl, when heated, dilates in a direction perpendicular to the axis, and contracts in the direction of the axis; there will consequently be an intermediate direction in which no dilatation takes place, and in this he proposes to cut his standard rules. Some observations on the constitution and movement of glaciers, by MM. C. Grad and A. Dupré, were presented by M. Leverrier. The authors investigated the structure of the ice of the great Aletsch and other glaciers at different points of their course, and found that in all cases the size of the grains or constituent elements of the ice gradually increased from above downwards. They also noted the movements of the Aletsch glacier at those points of its course, and the amount of surface loss which it underwent by the action of the sun in the latter part of August, when their observations were made. A note by M. J. B. Baille on the heat reflected by the moon, was presented; the author confirms the results obtained by MM. Piazzi Smyth, Marié Dacy, and Lord Rosse. A notice of a new synthesis of guanidine, by M. G. Bouchardat, was presented. The author, in repeating M. Natauson's experiment for the production of urea by the action of gaseous ammonia upon oxychloro-carbonic gas, found that other amides of carbonic acid were produced, especially guanidine, the sulphate of which he obtained crystallised. Melanuric and cyanuric acids are also produced. M. C. Dareste communicated a note on arrest of development regarded as the proximate cause of most simple monstrosities; M. Bonchut read a note on hydrate of chloral, with especial reference to its physiological action, which led to some remarks by MM. Bussy and Dumas. An extract from a report by M. Gauldrée Boilleau on the recent earthquakes, and a fresh outbreak of yellow fever at Peru, was read, a note on the etiology of goître, by M. D. Brunet; a note on the phosphorescence of the sea, by M. Duchemin; and a note on the causes of the mortality of new-born infants and on the means of restraining it.

Prague

Royal Society of Bohemia—Natural Science Section, October 6.—M. E. Weyr read a memoir on the conic sections inscribed or circumscribed upon a triangle, having a double contact with a fixed conic section.

October 27.—Dr. E. Schöbe read a paper on the discovery of the terminations of the nerves in the wings of the Chiroptera. The well-known power possessed by bats of finding their way thro' gh numerous small obstacles, even when blinded and deafened, has led several anatomists to seek for the nervous apparatus by which this great sensibility is attained. Cuvier described a complete nervous network in the wings; but what he took for nerves, turn out to be elastic trabiculæ. Leydig and Krause have also published upon this subject. The author describes the wings in several genera of bats as composed of a duplication of the general integument, in which the two layers of cutis become amalgamated. The epidermis consists of a single layer of lineagonal cells, and the *rete Malpighianum* of two layers of cells, the upper ones large, polymorphic, and filled with colouring matter. The cutis contains very complete systems of elastic trabiculæ and striated muscles, and a vascular system, which were described in detail by the author, as also the hair-follicles, each surrounded by 7 or 8 sebaceous glands, and a hydrotic gland. Each wing has from 8,000 to 10,000 hairs, with their glandular systems. The nervous system is very highly developed and delicate. The principal branches follow the direction of the great vessels; the last ramifications, composed of from 8 to 12 fibrillæ, issue from the neurilemma, and form bundles, each consisting of 4 fibrillæ. Each bundle runs to a hair-follicle; two of its fibrillæ surround this in a loop, and terminate in a stratiform, *terminal papilla*, formed by the twisting of the fibrillæ into a ball; the other two interlace with the free fibrillæ of adjacent follicles, and form an extremely delicate terminal nervous network. The terminal papillæ are compared by the author to those in the human skin; he has sought and found papillæ also in the mouse, shrew, and mole. Dr. A. Fritsch announced the discovery of a new reptile, or batrachian, in the coal of Nyran, in the south-west of the carboniferous basin of Pilsen. The head is triangular, less elongated than that of *Archegosaurus;* the orbits are large; the lower jaw furnished with denticles; the vertebræ numerous, very close and equal, and the anterior limbs slender, and but little developed. The animal was probably about a foot in length. It is compared by the author with the well-known *Proteus anguinus* (= *Hypochthon Laurentii*).

SCHAFARIK

DIARY

THURSDAY, November 11.

London Institution, at 7.30.—On Architecture, or the Fine Art of Building: Prof. Robert Kerr.

Zoological Society, at 8.—On the Anatomy of the Aard-Wolf (*Proteles cristatus*: Prof. Flower, F.R.S.

London Mathematical Society, at 8.—General Meeting at Burlington House.

FRIDAY, November 12.

Astronomical Society, at 8.

MONDAY, November 15.

London Institution, at 4.—Elementary Physics; Prof. Guthrie.

TUESDAY, November 16.

Statistical Society, at 8.—Inaugural Address by the President: W. Newmarsh, F.R.S. Report on the International Statistical Congress of 1869: Mr. Samuel Brown.

Institution of Civil Engineers, at 8.—Discussion on Mr. Gandard's Paper on the Strength and Resistance of Materials; and, time permitting, Public Works in the Province of Canterbury, New Zealand: Mr. Edward Dobson, Assoc. Inst. C.E.

WEDNESDAY, November 17.

Meteorological Society, at 7.—Lunar Influence upon Rainfall: Mr. J. C. Bloxam, M.R.C.S. On the Summer of 1868; Dr. G. H. Fielding.

THURSDAY, November 18.

Royal Society, at 8.30.

Linnean Society, at 8.—Review of the genus *Hydrolea*, with descriptions of three new species: Mr. A. W. Bennett, F.L.S.

Chemical Society, at 8.

London Institution, at 7.30.—Architecture: Prof. R. Kerr.

BOOKS RECEIVED

English.—Cassell's Technical Manuals: Projection, Linear Drawing, Building, Construction (Cassell).—Our Houses (Cassell).—First Book of Indian Botany: Prof. Oliver (Macmillan).—Via Medica: B. Langley (Hardwicke).—Wonders of Italian Art: Louis Viardot (Sampson Low).—What is Matter? Inner Templar (Wyman and Sons).—Essays on Physiological Subjects: G. W. Child (Longmans).—Phenomena and Laws of Heat: A. Cazin, translated by E. Rich (Low).—Thunder and Lightning: W. De Fouvielle, translated by T. L. Phipson (Low).—Wonders of Optics: F. Marion, translated by C. W. Quin.—Tommy Try and what he did in Science (Chapman and Hall).

American.—Origin of Genera: E. A. Cope (Trübner).—Annual Report of the Trustees of the Museum of Comparative Zoology at Harvard College.

Foreign.—Vierteljahrsschrift der Astronomischen Gesellschaft.—Les Pierres, Esquisses Minéralogique: L. Simonin (Hachette).—Bibliothèque des Merveilles: 4 vols. (Hachette).—Dictionnaire Général des Sciences: Privat-Deschanel et Ad. Focillon.—Untersuchungen über einige merkwürdige Thiergruppen des Arthropoden-und Wurm-Typus: Dr. R. Greeff.—Handbuch der Edelsteinkunde: Dr. A. Schrauf (Through Williams and Norgate).

Every Thursday, in Royal 8vo., price 4d., No. I. published November 4, 1869.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"*To the solid ground*
Of Nature trusts the mind that builds for aye."—WORDSWORTH.

THE object which it is proposed to attain by this periodical may be broadly stated as follows. It is intended,

FIRST, to place before the general public the grand results of Scientific Work and Scientific Discovery; and to urge the claims of Science to a more general recognition in Education and in Daily Life;

And, SECONDLY, to aid Scientific men themselves, by giving early information of all advances made in any branch of Natural knowledge throughout the world, and by affording them an opportunity of discussing the various Scientific questions which arise from time to time.

To accomplish this twofold object, the following plan will be followed as closely as possible:

Those portions of the Paper more especially devoted to the discussion of matters interesting to the public at large will contain:

I. Articles written by men eminent in Science on subjects connected with the various points of contact of Natural knowledge with practical affairs, the public health, and material progress; and on the advancement of Science, and its educational and civilizing functions.

II. Full accounts, illustrated when necessary, of Scientific Discoveries of general interest.

III. Records of all efforts made for the encouragement of Natural knowledge in our Colleges and Schools, and notices of aids to Science-teaching.

IV. Full Reviews of Scientific Works, especially directed to the exact Scientific ground gone over, and the contributions to knowledge, whether in the shape of new facts, maps, illustrations, tables, and the like, which they may contain.

In those portions of "NATURE" more especially interesting to Scientific men will be given:

V. Abstracts of important Papers communicated to British, American, and Continental Scientific societies and periodicals.

VI. Reports of the Meetings of Scientific bodies at home and abroad.

In addition to the above, there will be columns devoted to Correspondence.

The following eminent Scientific men are among those who have already promised to contribute Articles, or to otherwise aid in a work which it is believed may, if rightly conducted, materially assist the development of Scientific thought and work in this country:—

ABEL, F. A., F.R.S. *H.M. Chemical Department, Woolwich.*
AGASSIZ, PROF. L. *Museum of Comparative Zoology, Harvard College.*
ANDREWS, PROF. T., F.R.S. *Queen's University, Dublin.*
BASTIAN, PROF. H. C., F.R.S. *University College.*
BEALE, PROF. LIONEL S., F.R.S. *King's College.*
BENNETT, A. W., F.L.S.
BERTHELOT, PROF. *Collége de France, Paris.*
BONNEY, REV. T. G. *Cambridge.*
BRADY, H. B., F.L.S.

CONTRIBUTORS—continued.

THURSDAY, NOVEMBER 18, 1869

LECTURES TO WORKING MEN

THE workmen of England wish for more education. I speak of the better classes of them; those who can read and write and cast up accounts in some sort of fashion, though it may in many cases be a poor one. There is a great desire, which is very widely spread among them, for some kind of higher education: they wish to learn something of Science. They cannot learn it at school, and they cannot get all they want from books; so that they must look to a great extent for what they require to evening lectures. Now in these there are two things which they dread. The first is that they should only hear a string of technical terms, which they cannot understand; and the second is that they should have what ordinarily go by the name of "Popular Lectures on Science," lectures which are often illustrated by inconsequent "experiments." We have not to go far to find the reason of their dislike to such lectures: the fact is, they distrust them. The English workman is a clear-headed, shrewd man, and he has a good intuition of what is worth having. That is the reason he cares for scientific knowledge. He knows very well that science is "one of the best things going;" and he has also a very thorough appreciation of everything of the nature of humbug in any line whatsoever. Perhaps there is no audience in the world who, on the one hand, recognises readily the existence of humbug, and, on the other, recognises what is genuine, so well as an audience of intelligent English working men. I have often conversed with such men, and while I have heard them express the greatest desire for scientific information, I have heard them also speak most disrespectfully of that which is too often presented to them instead of it; and I have, over and over again, heard this said, "What is the use of our going to lectures, when we are to hear no more of the subject again?" Such sentiments as these find practical expression in the fact that I have found courses of a few consecutive and carefully digested lectures to workmen always well attended by a persistent audience. It is nothing desultory that these men want, but something solid—something which will give them real information. What they want is not a single lecture, or bits of the thing shown to them in a random sort of way, but a piece of real teaching, something which helps them to see their way a little through some subject, and gives them a better grasp of the thing which they are seeking for, namely, the method and facts of science. To be told only a number of the facts and results of science without the method is what workmen do *not* want; they are greedy for the facts of science, but they want something more. On the other hand, to try to impart to them the method of science without doing so by some particular instance, is to engage them in a kind of vague philosophising, suitable perhaps for the learned, but not for the ignorant. Ignorant people do not want, and cannot profit by, abstractions.

I believe, therefore, that a real demand amongst working men is supplied by short courses of lectures on scientific subjects, given in the evenings in some Institute or Mechanics' Hall. The lectures should not occur more than twice, or perhaps once, a week. We must never forget that it is a hard matter for a working man to get to a lecture in an evening. To give such a set of lectures to working men calls for those who are well versed in the subject with which they are to deal; for it is only such who can speak free from technicalities. It must be remembered that workmen have no previous information, no knowledge of mathematics or of technical terms, which may enable us to shorten demonstrations or explanations. Everything requires to be explained to them *ab initio;* and it is only a man well versed in the subject down to the minutest particulars who can do this well. It is only such a man who can bring forward the first rudiments of a subject shortly, distinctly, and so as to interest his audience, *without being superficial.* Others speak from too bare a mind. But a man deeply versed in a subject can put it in a perfectly elementary way, and yet weave about it the interest of its most advanced portions. We have to show workmen the main points of an argument; they cannot come to, nor can we afford to give them, thirty or forty lectures, as we should do at the University. We can only give them three or four, and we must do the best we can in these. The best we can do seems to me to be this, to choose from the branch of science, which we wish to bring before them, some one of its most characteristic parts; and, while following out the great steps of that particular argument, to so illustrate it as to suggest and open up the rest of the subject, at the same time taking care to bring all to bear on one thing. A great point to aim at is, that all that we speak about should have a relation to the subject in hand, and such a relation as our audience will easily perceive—that we should not, in fact, bring before them isolated facts or theories, but always something connected, something logical. This indeed is the great end of teaching science: to get people into a better style of thinking about things; and this is just what, as soon as these men find it, they greedily snatch at; for they aim at some knowledge of science for a reason which is perhaps not quite clear to their own minds; but when they get the thing they want, they recognise that it is what they want.

Our English workmen, in fact, have not quite enough logicalness about them. They are apt to be led away by wrong arguments, by conclusions which do not quite follow from the premises. And, what is more, they (at least the best of them) know that quite well. And that is just the very point where some instruction in science helps them; where the scientific method—the method of getting hold of facts and putting them together, and doing so in a strict and careful way—helps people. And this is just what the workmen of this country need, and what a large number of them feel that they need, and the very reason for which they desire scientific knowledge. Now where this desire exists, do not let us hear them ask for bread and give them a stone. The future of England depends on these men. They are hard-headed, honest, straightforward men; and they think a deal; and they have got their faults, and not the least of them is this fault of being somewhat illogical. I have heard both employers and workmen say, "It is because our men are too apt to be led away by inconclusive arguments, that half the errors which they commit are committed." To any one who has studied the matter of the failure of so many workmen's Benefit Societies, the truth of these remarks will be evident. I am not here expressing any opinion as to the rights or wrongs of many things at which workmen aim, and in which they engage. But totally irrespective of opinion, it is evident that there are many important questions the management and the decision of which are in the hands of the working men, and a right view of the respective importance of facts and of argument is the only safeguard against being misled. It is just at this very point that scientific teaching helps to set men right. I am not saying whether or not I believe that Science is to be the regenerator of mankind. But this is certain, that there is a great benefit to be gained from scientific teaching, that it supplies to working men that which as a class they are deficient, and that which as a class they are desirous of having; and that here there is open before all who care for these matters a wide field of direct and immediate utility.

I have seen six hundred men, on a tempestuous winter evening, come to a lecture on Astronomy at one of our great workshops in the North. It is a wonderful sight to see so many faces intelligent and seeking for knowledge. Working men are a peculiar audience: they are rather fond of cheering; and I have often had to check a piece of applause arising just before the conclusion of a demonstration which was tying together, so to speak, in a knot, several threads of argument. Such applause, coming, as I have so often seen it, *just before* the completion of an argument, indicates the satisfaction which all feel, and which these men are unsophisticated enough to express, when there just begins to dawn upon them the feeling of seeing, without being told, what some things have got to do with one another; the feeling in fact of making a discovery. And I can fancy nothing more encouraging to a lecturer who loves his subject than such facts, and nothing which more bears out the assertion that I have made, that there is among working men a true desire for, and a true appreciation of, something genuine in science. Working men—at least those with whom I am acquainted, and I am acquainted chiefly with the northern districts of England—have a strong perception of right and wrong, a strong moral character, a clear and open way of giving everything a fair hearing—that natural honesty which is the backbone of a nation. And if we add to this the powerful logic and the wide information which the true teaching of science imparts, we bid fair to make the democracy of England a model for that of all other countries.

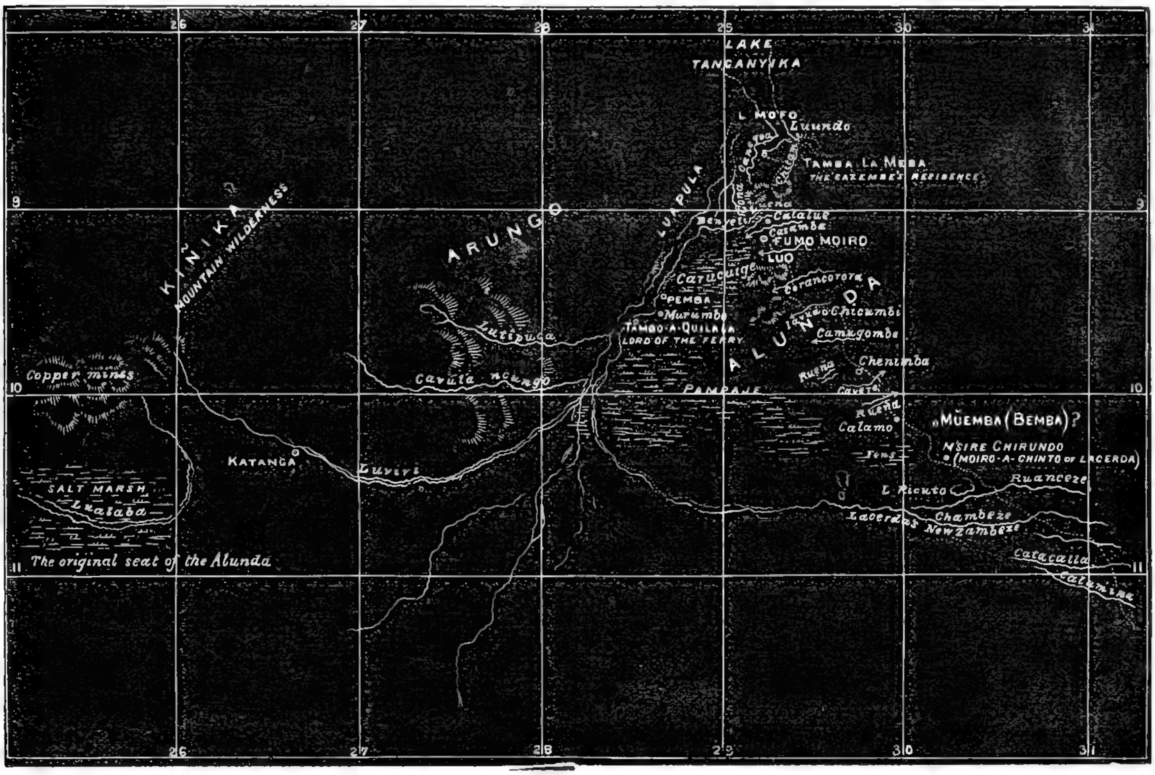
JAMES STUART

DR. LIVINGSTONE'S EXPLORATIONS

THE letters from Dr. Livingstone lately read at the Royal Geographical Society, give the grateful assurance, not only that he was in good health and spirits in July 1868, but also that he was under no apprehension of ill-treatment from the Cazembe. Visiting that chief without a numerous escort, he created no alarm. He has, in truth, notwithstanding seeming difficulties, been singularly fortunate; for his rumoured death and expected captivity have created a sensation of much greater value to him than the discovery of the Nile's sources. Dr. Livingstone's account of his journey northwards from the Aroangoa is in general reconcilable with those given by the Portuguese expeditions, with some difference, however, arising from difference of route. He seems to have crossed that river much further to the west than Monteiro, whose line of march was ten or twelve miles more west than that of Lacerda. He saw mountains, he tells us, and the Portuguese saw none. Herein he is greatly mistaken: Monteiro's expedition crossed over the flanks of a wondrous mountain, supposed to be a Portuguese league (about 20,000 feet) high, with trees, population, but no snow on its broad summit. The account of this mountain, called by mistake Muchingue (the glen or defile), given by a writer in the Journal of the Royal Geographical Society (vol. xxvi.), improves the original by a precise statement of longitude and latitude, and by a description of the panoramic view from the summit to a distance of 200 miles.

The high land which culminates towards the east in Muchingue was ascended on leaving the valley of the Aroangoa. The traveller then came in lat. 10° 34′ S., to the river Chambezi, called by Lacerda the New Zambezi, flowing from east to west, and rarely fordable. He remarks that it resembles the Zambezi, not in name only, but also in the abundance of food found in the stream or on its banks. He forgets that the critic who denied his explanation of the name Zambezi (river *par excellence*), showed that in all its forms, Liambegi, Chambezi, Yabengi, &c., it means simply (river) "of meat" or animal food. The Chambezi abounds in oysters, but we know nothing of their flavour. This river, according to Dr. Livingstone, forms in the west the great Lake Bengweolo, from which it again issues to the north under the name of Luapula; but we believe it would be more correct to say that it joins the Luapula, a much larger river, the great marsh Pampage, which is, doubtless, often overflowed and converted into a lake, lying in the angle between the two rivers. Then we are told—"The Luapula flows down north past the town of Cazembe, and twelve miles below it enters the Lake Moero." From this it might be concluded that the river flows by the chief's town, and that twelve miles lower down, or further north, it enters the lake, but this cannot possibly be the traveller's meaning. Lake Moero forms a remarkable feature in Dr. Livingstone's latest discoveries, but his account of it is singularly perplexed and obscure. We know that the Luapula flows to the north or N.N.E., some eight or ten miles west of the Cazembe. Lake Moero, by our traveller's account, is fifty miles long, and from 30 to 60 miles wide. "Passing down," he says, "the eastern side of Moero, we came to the Cazembe;" and again he states that "the Cazembe's town stands on the north-east bank of the lakelet Mofwe, two or three miles broad and four long, totally unconnected with Lake Moero." In endeavouring to reconcile these statements it is necessary to beware of rash conclusions and inaccurate expressions. It is a hazardous thing to pronounce upon the length, breadth, and boundaries of lakes without surveying them. The Portuguese officers in 1831 obtained leave to examine Lake Mofo or Mofwe, and for that purpose went four and a half leagues N.N.E. along its shore, till they came to the Lounde, a river, as they called it, two miles wide, where they expected to find boats. These, however, had been purposely removed, so that the explorers were brought to a stand. They had proceeded far enough, however, to perceive that the lake turned to the north-west. They did not see the end of it, but state distinctly that it communicates with other large lakes. Dr. Livingstone, describing the flooded state of the country, tells his experience of two rivers which flow into the north end of Moero: the Luo, which was crossed by the Portuguese, thirty miles south of the Cazembe's town; and the Chungu, near which Lacerda died, about ten miles south of that place. From these particulars we cannot help concluding that the Moero of our traveller, who has found the country in a state of flood, is the Carucuige of the Portuguese, or at least that these names apply to parts of the same great marsh or lagoon. At the eastern side of it, visited by Dr. Livingstone, is the Fumo Moiro, whose title is probably taken from his district. Manoel Gaetano Pereira, who first visited the Cazembe, related, that near the chief's town he spent a whole day wading breast-deep through a lagoon. It was subsequently found that the lagoon in question was Carucuige. The strength of the Cazembe's position lies in the difficulty of approaching it through a labyrinth of swamps, lakes, and wide drains. The Portuguese spent some hours in crossing a river, as they called it, two miles wide, on matted vegetation which sank under their feet. This and the Loûnde above mentioned were probably the connecting arms of large lakes.

Our traveller informs us, that "the Luapula, leaving Moero at its northern end by a rent in the mountains of Rua, takes the name of Lualaba, and, passing on N.N.W., forms Ulenge in the country west of Tanganyika." He saw the Luapula only at this gap in the mountains. Ulenge is a lake with many islands, or a separation of the river into many branches. "These branches," he goes on to say, "are all gathered up by the Lufira. . . . . I have not seen the Lufira; but, pointed out west of 11° S., it is there asserted always to require canoes. . . . . This is purely native information." Now it is quite possible that the traveller totally misunderstood his native informants. They spoke of the waters to the S.W., and he understood them to speak of the N. or N.E. The great river Luviri, called by the Arabs Lufira, flows into the Luapula from the west, about 100 miles S.W. or S.S.W. from the Cazembe. The Lualaba, the sacred river of the Alunda, whence their forefathers emigrated, still farther west (a month's journey), falls into the Lulua, and so joins the Zaire. The great salt marshes, which chiefly supply the interior of Africa, are situated on its banks at its southern bend; these may be the Ulenze above described, if it be not a marshy tract lying between the sources of the two rivers. The native information here given cannot be received as perfectly pure. When our author speaks of the Luviri entering Tanganyika at Uvira, he evidently casts the dimly discerned views of the natives into his own preconceived mould, and clothes them in his own language.



Respecting the language of this country, our author informs us that "the people are known by the initial Ba instead of the initial Lo or U for the country." This is not merely confused, but also, we believe, wholly erroneous. The initial U never forms the name of a country, but the collective name of a nation, chief, and people. The Portuguese, who on this point are the best authorities, use the names Alunda, Arungo, Acumbe, not Balunda, &c. They tell us that the Alunda never pronounce the letter r, and that in writing the names Arungo, Moiro, &c., in which that letter occurs, they have adhered to the Maravi dialect. We thence conclude that for the names Rua, Moero, Lufira, &c., and perhaps for the initial Ba above alluded to, Dr. Livingstone is probably indebted to his Arab friends, who rest satisfied with a jargon, in some degree intelligible everywhere, and nowhere perfect.

Dr. Livingstone seems to be elated with the discovery that "the chief sources of the Nile arise between 10° and 12° S. lat., or nearly in the position assigned to them by Ptolemy, whose river Rhapta (?) is probably the Rovuma." Here two different problems are attempted to be solved at once—one touching the Sources of the White Nile, and the other, those of Ptolemy's Nile. With respect to these latter, it will be enough to observe that Ptolemy's Lakes of the Nile, two in number, 8 degrees asunder, are placed by him respectively in lats. 6° and 7° S., but his graduation being defective, through an imperfect estimate of the length of a degree, the positions thus assigned to the lakes fall under true graduation, to 11″ N., and 40″ S. of the equator. Ptolemy's Lakes, therefore, have not been reached by the zealous traveller.

With respect to the sources of the Bahr el Abyad, they may of course be traced to the head waters of the Luapula, provided that the results of Capt. Burton's observations on the altitude of Nyanza and the character of its northern end are completely thrown aside. With a greater elevation, and an outlet through Speke's Mountains of the Moon, the waters of the lake may reach Egypt.

It is to be regretted that Dr. Livingstone missed the opportunity of viewing the highest mountain in this part of the world, now known only by a ridiculously exaggerated description; and also a most interesting point in the centre of Africa. The great town, Katanga, as described by the Arabs, is near the copper mines, where 75 lbs. of copper may be bought for 4 cubits of American sheeting. The town is larger than Roonda (the Cazembe's town), and has good bazaars; it stands on the Rafira (Luvira) which joins the Ruapura (Luapula). The people are peaceable, and kind to strangers. The people from Zanzibar learned the language almost immediately.

F.R.G.S.

[We give a map of the region recently traversed by Livingstone, showing its connection with the known points in this part of Africa. We owe this map to the courtesy of the officers of the Royal Geographical Society. —Ed.]

CUCKOWS' EGGS

SCARCELY any bird has so much occupied the attention, not merely of naturalists, but of people generally, as the Common Cuckow of Europe, and (we might almost add, consequently) scarcely any bird has had so many idle tales connected with it. Setting aside several of its habits wherein it differs from the common run of birds, its strange, and, according to the experience of most persons, its singular mode of entrusting its offspring to foster-parents, is enough to account for much of the interest which has been so long felt in its history. Within the last twenty years a theory (which is, as I shall presently show, by no means a new one) with respect to an important fact in its economy, has attracted a good deal of attention, first in Germany, and latterly in England; and as this theory seems to be especially open to misconception, and in some quarters to have been entirely misunderstood, I shall endeavour to give an account of it in a manner more distinct than has yet (I think) been done; and to show that there is no good ground for believing it to be irrational, as some have supposed, and for scouting it as something beneath contempt.

It has long been notorious to oologists that the eggs of the Cuckow are subject to very great variety in colour, and that a large number of birds laying eggs of very different colours enjoy the doubtful advantage of acting as foster-parents to the young Cuckow. Now the theory to which I refer is that "the egg of the Cuckow is approximately coloured and marked like those of the bird in whose nest it is deposited, that it may be the less easily recognised by the foster-parents as a substituted one."

This theory is old enough, for it was announced and criticised nearly a hundred years ago by Salerne,* who, after mentioning that he had seen two Stonechats' nests, each containing eggs of that bird, as well as a Cuckow's (which was as blue as the others, but twice [?] as large), goes on to say that he was assured by an inhabitant of Sologne (a district in France to the south of Orleans), that the Cuckow's egg is always blue; and then comes this remarkable statement:—"As to the assertion of another Solognot who says that the hen Cuckow lays its eggs precisely of the same colour as those in the nest of which she makes use, it is an incomprehensible thing." Many of my readers will, I doubt not, be at once inclined to agree with Salerne.

Little attention seems to have been paid to this passage by succeeding naturalists;† but in 1853 the same theory was prominently and (I believe) independently brought forward by Dr. Baldamus, then editor of *Naumannia*, a German ornithological magazine, now defunct; so far as I know, however, it was not until April, 1865, that an article in the English ornithological journal, the *Ibis*, by Mr. Dawson Rowley, gave anything like an idea of it to the public of this country. Some months later (14th September) Mr. A. C. Smith introduced the subject to the Wiltshire Archæological and Natural History Society, and the paper he then read, having been since printed in the *Wiltshire Magazine* (vol. ix. p. 57), and elsewhere, has, with Mr. Rowley's article, made the theory very generally known. Mr. Smith also published, subsequently, in the *Zoologist* for 1868, a translation of Dr. Baldamus's elaborate essay; but this translation being unaccompanied by the coloured plate which illustrated the original, unfortunately fails to do justice to the Doctor's theory, for without seeing the specimens on which this is founded, or good figures of them, the evidence in its favour can scarcely be appreciated fully.

Dr. Baldamus's theory had been some time known to me, when in 1861 I had the pleasure of being shown by him his collection of Cuckows' eggs, and I can declare

* L'histoire naturelle, éclaircie dans une de ses parties principales, l'ornithologie, &c. Paris; 1767, p. 42.

† Montbeillard (Hist. Nat. des Ois, vi. p. 309) mentions it, but I am not aware of any one else who has done so, until M. Vian in the *Revue et Magasin de Zoologie* for 1865 (p. 40), referred to it, and from this reference I became acquainted with it.

that his published figures represent the specimens (sixteen in number) from which they are drawn, as faithfully as figures of eggs usually do, and that an inspection of the series convinced me that the belief he entertained was not groundless. All the eggs in question, some departing very widely from what I had been used to regard as the normal colouring, bore an unmistakable resemblance to those of the birds in the nests of which they were asserted (in most cases, I was assured, on very good authority) to have been found; while in some cases there was just enough difference between them and those they "mimicked," to show that it was far more unlikely that they should have been extraordinary varieties of the eggs of the species in question, than eggs of the Cuckow.

Dr. Baldamus's allegation therefore seemed to me to be in part proved. If the history of the eggs before me could be trusted—and I had no reason to doubt it, the fact of the likeness was in many respects self-evident, in others certainly not so striking, and in some perhaps questionable. In further corroboration of the theory also, there were the similar instances cited with much assiduity from foreign sources by Dr. Baldamus in his essay,* and one, apparently not known to him, but given by Mr. Blyth in Sir William Jardine's "Contributions to Ornithology" for 1850 (p. 69 *bis*, pl. 52). Another and very remarkable case had also come to my own knowledge. In the autumn of 1857 I had received from Mr. Tristram all the eggs collected by him in Algeria during the preceding season. When they were unpacked, it appeared that there were two more specimens of the egg of a large North-African Cuckow (*Oxylophus glandarius*) than I had been led by him to expect. On examination, I found that the first two eggs of this species which had been obtained by him so much resembled eggs of the Magpie of the country (*Pica mauritanica*), in the nests of which they had been found, that, skilful oologist as he was, they had passed, even to his practised though unsuspecting eye, as those of the latter bird. Had I known then of Salerne's words, I should have exclaimed with him, "c'est une chose incompréhensible!"

Having said thus much, and believing as I do the Doctor to be partly justified in the carefully-worded enunciation of what he calls a "Law of Nature," I must now declare that it is only "approximately" and by no means *universally* true that the Cuckow's egg is coloured like those of the victims of her imposition. Increase as we may, by renewed observations, the number of cases which bear in favour of his theory, yet, as almost every bird's-nesting boy knows, the instances in which we cannot, even by dint of straining our fancy, see resemblances where none exist, are still so numerous as to preclude me from believing in the generality of the practice imputed to the Cuckow. In proof of this I have only to mention the many eggs of that bird which are yearly found in nests of the Hedge-Sparrow in this country, without ever bearing the faintest similarity to its well-known green-blue eggs. One may grant that an ordinary English Cuckow's egg will pass well enough, in the eyes of the dupe, for that of a Titlark, a Pied Wagtail, or a Reed-Wren, which, according to my experience, are the most common foster-parents of the Cuckow in this country; and indeed one may say, perhaps, that such an egg is a compromise between the three, or a resultant, perhaps, of three opposing forces; but any likeness between the Hedge-Sparrow's egg and the Cuckow's, so often found along side of it, or in its place, is not to be traced by the most fertile imagination. We must keep therefore strictly to the letter of the law laid down by Dr. Baldamus, and the practice imputed to the Cuckow is not universally but only "approximately" followed.

* I do not here enumerate them; they will be found in *Naumannia* for 1853, p. 317, note. The plate which illustrates the paper is in the volume of the same magazine for the following year.

Now, is it possible to give a satisfactory explanation of the process by which the facts alleged are produced? Dr. Baldamus assigns none. He lays down a number of aphorisms, most of which are very interesting, and, I believe, true; but they do not touch the question. A good many people who have only read hastily, and still more those who have to all appearance only read at second or third-hand what has been written on the subject, seem to imagine that the Doctor has wished to assert that the Cuckow can voluntarily influence the colour of her egg, so as to assimilate it to those already in the nest in which she is about to deposit it.* Dr. Baldamus, indeed, mentions such a supposition, but expressly says that he rejects it, and herein I think that nearly every physiologist will agree with him.

It will be admitted, I think, that Dr. Baldamus's inference as to the object of the practice being that the Cuckow's egg should be "less easily recognised by the foster-parents as a substituted one," is likely to be true. This being the case, only one explanation of the process can to my mind be offered. Every person who has studied the habits of animals with sufficient attention will be conversant with the tendency which certain of those habits have to become hereditary. It is, I am sure, no violent hypothesis to suppose that there is a very reasonable probability of each Cuckow most commonly placing her eggs in the nests of the same species of bird, and of this habit being transmitted to her posterity. Without attributing any wonderful sagacity to the Cuckow, it does seem likely that the bird which once successfully deposited her eggs in a Reed-Wren's or a Titlark's nest should again seek for another Reed-Wren's or another Titlark's nest (as the case may be), when she had an egg to dispose of, and that she should continue her practice from one season to another. We know that year after year the same migratory bird will return to the same locality, and build its nest in almost the same spot. Though the Cuckow be somewhat of a vagrant, there is no improbability of her being subject to thus much regularity of habit, and, indeed, such has been asserted as an observed fact. If then this be so, there is every probability of her offspring inheriting the same habit, and the daughter of a Cuckow which always placed her egg in a Reed-Wren's or a Titlark's nest doing the like.

Further, I am in a position to maintain positively that there is a family likeness between the eggs laid by the same bird, even at an interval of many years. I know of more than one case in which a particular Golden Eagle has gone on season after season laying eggs that could be at once distinguished by a practised eye from the eggs of almost any other Golden Eagle; and I know of one case

* Thus Mr. Cecil Smith (not to be confounded with Mr. A. C. Smith, before mentioned) in a work published within the last few weeks, falls into this mistake ("Birds of Somersetshire," p. 265), after having stigmatised the Doctor's theory as "wild," which he well might if it had been as it is represented.

in which the presumed daughter of a particular Golden Eagle, remarkable for having produced eggs of very great beauty, has in two successive years laid eggs which unmistakably resembled those of her reputed mother in the brilliant character of their colouring.

Hence I am not afraid of hazarding the supposition, that the habit of laying a particular style of egg is likely to become hereditary in the Cuckow; just as I have previously maintained that the habit of depositing that egg in the nest of a particular kind of bird is also likely to become hereditary.

Now it will be seen that it requires but only an application to this case of the principle of "Natural Selection" or "Survival of the Fittest" to show that if my argument be sound, nothing can be more likely than that, in the course of time, that principle would operate so as to produce the facts asserted by the anonymous Solognot of a hundred years ago, and by Dr. Baldamus and others since. The particular *gens* of Cuckow which inherited and transmitted the habit of laying in the nest of any particular species of bird eggs having more or less resemblance to the eggs of that species, would prosper most in those members of the *gens* where the likeness was strongest, and the other members would (*cæteris paribus*) in time be eliminated. It is not to be supposed that all species, or even all individuals of a species, are duped with equal ease. The operation of this kind of "Natural Selection" would be most marked in those cases where the species are not easily duped, that is, in those cases which occur the least frequently. Here it is that we find it, for it has been shown that eggs of the Cuckow, deposited in the nests of the Red-backed Shrike, of the Bunting-Lark, and of that bird which for some reason best known to the donor bears the English name of "Melodious Willow-warbler," approximate in their colouring to the eggs of those species—species in whose nests the Cuckow rarely (in comparison with others) deposits her eggs. Of species which would appear to be more easily duped, or duped in some other manner—the species in whose nests Cuckow's eggs are more commonly found, I may have something to say in another paper.

ALFRED NEWTON

THE ORIGIN OF BLOOD-LETTING

THE flamingo in the gardens of the Zoological Society has recently been observed to vomit a red-coloured fluid over certain smaller birds kept with it; and it has been shown that this red fluid contains true blood-corpuscles, and inferred that the flamingo is in the habit of feeding its young by this ejection of a blood-stained "pigeon's milk" into their mouths. Further, the habit of the flamingo has been with great probability connected with the story of the pelican, which, as is well known, is stated to wound its own breast in order to feed its young with the blood. It is not at all improbable that birds so alike in their plumage and habitat as the pelican and flamingo should be confused in the way suggested by Mr. Bartlett, who, I believe, first observed the habit of the captive flamingo. The extravasation of *blood corpuscles* normally from the pharynx or œsophagus of such an animal is a matter of great interest. Mr. Lowne has a paper in the Journal of the Queckett Microscopical Club, in which he gives a full account of the case, having examined the bloody exudation microscopically. To this the reader is referred; but I have something to add to it.

The connection of the flamingo with the classical story of the pelican's self sacrifice is increased in interest, since it appears that the red exudation of the hippopotamus is connected with an equally ancient and more important tradition—namely, the history of the origin of blood-letting. Before giving this tradition, I would mention that two years since, by the kindness of Dr. Murie, I obtained some of the red exudation of the hippopotamus on a slip of glass, and on examining it with the spectroscope, I did *not* obtain a blood-spectrum. Mr. Tomes (Proc. Zool. Society, 1857) described the microscopic appearances of the exudation of the hippopotamus, and stated that he found in it remarkable corpuscles with pigmentary granules, but not *blood corpuscles*. The folds of the skin in various parts of the body of the hippopotamus are coloured bright pink by a distinct pigment, and the same tint suffuses the darker parts of the skin. I believe it is this pigmentary matter which causes the red colour of the exudation of the hippopotamus, and that it is not a sweat of blood at all. The case of Mr. Jamrack's rhinoceros mentioned by Mr. Lowne may be otherwise. Mr. Lowne says that cases of blood-stained sweat from the skin of man are, though rare, well authenticated. This is perhaps true; but many apparent cases of such staining are due to the formation of a purpurate in the sweat, from the decomposition of the uric acid which it contains.

Now, with regard to the hippopotamus, it is important to note how popular tradition has attributed the origin of a very valuable medical art to a totally false inference on the part of Egyptian priests.

M. Milne-Edwards, in the 3rd volume of his "Leçons sur la Physiologie" (p. 3), has the following note:—"Homer, whose poems constitute a sort of encyclopædia of the science which the Greeks possessed about the ninth century before Jesus Christ, does not speak of bleeding: but if we are to believe an author of the fifth century, Stephanus of Byzantium, this operation was known to the surgeons of the army of Agamemnon. In fact, he relates that one of them, Podalirius, son of Æsculapius, and brother of Machaon, on the return from the siege of Troy, practised it on a patient whose cure obtained for him the sovereignty of the Chersonese. This would be the first case of blood-letting of which the remembrance has been preserved; and, on consideration of a fable reported by Pliny, I am induced to believe that this practice had taken its rise in Upper Egypt: in fact, this naturalist tells us that the hippopotami, when they become too obese, have the habit of piercing for themselves the vein of the thigh, by pressing against a pointed reed; and that these animals have thus taught physicians to practise analogous operations. Now, this account does not apply to the sea-horse (or *Syngnathus*), as the author of an estimable work on the history of medicine (Leclerc) supposes, but to the great pachyderm which inhabits the rivers of the interior of Africa, and which is found in Upper Egypt. It is evidently a fable: but this fable could only have reached us from Egypt."

M. Milne-Edwards was not aware of, at any rate does not refer to, the red oozing observed on the skin of the hippopotamus sometimes after emerging from his bath, or when enraged, which gives so marked a confirmation to the Egyptian story. We may conclude fairly enough, either that the Egyptian priests saw this red exudation, and imitated it with the practice of bleeding, or, as is infinitely more probable, that the Egyptian laity noticed the blood-coloured sweat of the great river-horse, and connected it with the practice of bleeding then in operation, by the interpolation of the sharp reed, and an inability to understand that their wise men could discover a remedy untaught. E. RAY LANKESTER

PREHISTORIC ARCHÆOLOGY

Transactions of the International Congress of Prehistoric Archæology, 3rd Session, 1869. Royal 8vo, pp. 419, with 53 illustrations. (Longmans, 1869.)

IN these days of annual gatherings or Congresses intended for the promotion of Science, whether Natural, Social, or Ecclesiastical, we need not be surprised at the numerous observers now engaged in different countries in the various branches of Prehistoric Anthropology and Prehistoric Archæology founding an International Congress for the discussion of questions in which they are particularly interested. It was at a meeting of the *Société Italienne des Sciences Naturelles*, held at La Spezzia in 1865, that this Congress originated, with the more comprehensive than euphonious title of "Palæoethnological." With a slight change in its designation it met at Neuchâtel in 1866, and at Paris in 1867; while the Congress, the transactions of which are recorded in the volume before us, assembled at Norwich last year under the presidency of Sir John Lubbock, and with Colonel A. Lane Fox as organising secretary, contemporaneously with the meeting of the British Association. During the present year it has found a congenial home in the midst of the richly-stored museums of Copenhagen, under the fitting presidency of Professor Worsaae; has dug in the Kjökkenmöddings, and been right royally entertained by the King of Denmark; and next year the gathering is to be at Bologna, with Count Gozzadini as president. Such meetings, especially in the case of the followers of what must be regarded as a comparatively new science, serve at least a double purpose; as social gatherings they promote that intercourse and kindly feeling between those engaged in the same pursuit, which helps the onward progress of knowledge, while the discussions at the meetings tend to elicit truth from what may apparently be conflicting facts and opinions, and when too unruly hobby-horses are introduced into the arena, serve to control their wilder caracoles, if not effectually to break them in.

The success that has attended the institution of this particular Congress, which, by the way, is not to be held during two consecutive years in one country, cannot be better evinced than by the Report of its seven meetings at Norwich, which has just made its appearance, and forms a volume of upwards of four hundred pages, illustrated by more than fifty plates, for the most part presented by the authors of the papers they illustrate.

These Papers range over a wide area, both in space and time. The Pacific and South Sea Islands, the Cape of Good Hope and Southern and Western India, Japan and Algeria, as well as Spain, Portugal, France, Britain, and Ireland, all contribute their *quota* of facts; while various general questions relating to the condition, the arts, the distribution, and other circumstances of early races of mankind are brought forward and discussed. On the whole we may congratulate the Congress on the object of its assembly having been so carefully kept in view by the authors of the papers read before it, since hardly any of them, though varying much in value, can be regarded as having been irrelevant to its general purposes.

The time and space at our command being small in proportion to that ranged over by the Prehistoric Archæologists, we cannot give more than a brief notice of some few of what seem to us the more important papers; but at the outset we must express our regret, which we are sure many others will share with us, that the excellent Opening Address of the President was not more fully reported.

First of the Papers, and among the first in interest, is one by Mr. E. B. Tylor, on the "Condition of Prehistoric Races as inferred from Observation of Modern Tribes," in which some curious anomalies in the degree of knowledge in different branches of art and constructive appliances possessed by certain tribes are pointed out, and the inference drawn that it is unsafe to attempt to fix the stage of civilisation of any given people from the rudeness of one single class of implements in use among them.

Professor Huxley's Paper on the "Distribution of the Races of Mankind, and its Bearing on the Antiquity of Man," appears to have met with more favourable criticism from those present, including Professor Carl Vogt, than the author anticipated. And certainly the connection between some of the changes which in comparatively recent times have taken place in the physical geography of the earth, and the limitation of the areas occupied by different races, such as the Negroid and Australioid, seems, if not susceptible of proof, at least possible; and, if so, Professor Huxley's conclusion that the distribution of these two races of Man affords as strong evidence of his antiquity as the occurrence of his works in the gravel of Hoxne and Amiens is in a fair way of being adopted.

Touching these early works of man, we commend attention to the excellent account given by Mr. R. Bruce Foote, of his discoveries of quartzite implements of Palæolithic types in the Laterite formation of the east coast of Southern India. We know of nothing more striking than the wonderful similarity of these implements to those discovered associated with remains of extinct mammals in the old river gravels of Western Europe. But for the difference in the material there are numerous twin specimens so like each other that they might be thought to have been formed by the same hand, and yet they occur thousands of miles apart, and under what are apparently different geological conditions, though we think that much remains to be unravelled as to the origin and age of the Lateritic deposits of Madras. Still this parallelism of type seems to afford most remarkable proof that the same wants, with the same means at command for fulfilling them, result, so far as tools are concerned, in the production of similar forms, no matter where or when the men live who make them.

This is further illustrated by the stone implements from Japan, described by Mr. Franks, nearly all of which may be matched in form by arrow-heads, lance-heads, and hatchets found in Western Europe; and what is no less remarkable, the former are by the Japanese regarded as of heavenly origin, like the Elf-bolts of Scotland, and the stone-celts are considered to be thunderbolts—a belief so universal in historic times that it may be said to have been held *semper, ubique, et ab omnibus.* There is, in fact, no difference of opinion between the old Greek Sotacus and the Chinese Emperor Kang-hi's encyclopædist (A.D. 1662). The former informs us, through Pliny, as translated by Philemon Holland, that "there be two kinds of Ceauniæ, to wit, the black and the red," and, "that they doe resemble halberds or axe-heads." The latter that "some of the lightning-stones have the shape of a hatchet, others that of a knife, and some are made like mallets. They are of different colours; there are blackish ones, others are greenish."

The curious similarity observed among Megalithic monuments in different parts of the world may possibly be due to some analogous development of thought and feeling rather than to any intimate connection between the races who erected them. The Dolmens of Algeria, described by Mr. Flower, those of Brittany by Mr. Lukis, those of the Aveyron by M. Cartailhac, are all, more or less, closely allied to the ancient sepulchres and Pandukulis of the Nilagiri Mountains in Southern India, described by Sir Walter Elliot.

We cannot close this brief notice without mentioning one of the most carefully illustrated and important contributions to the volume,—the account of the caves of Gibraltar, in which human remains and works of art have been found, by Mr. George Busk, who, in company with the late Dr. Falconer, visited the scene of the explorations of Captain Brome, which are now unfortunately suspended, but of which the record drawn up by himself is here preserved, and additional value given to it by the commentary of Mr. Busk.

We have, we hope, said enough to show the interesting character of this volume of the Transactions of the Congress, and the reports of the meeting at Copenhagen lead us to hope that it may next year be productive of another volume of at least equal value.

JOHN EVANS

THE WORLD OF THE SEA

The World of the Sea. Translated and enlarged by the Rev. H. Martyn Hart, M.A., from "Le Monde de la Mer," by M. Moquin Tandon, Membre de l'Institut, &c. Demy 8vo. pp. 500, with coloured and tinted plates and numerous woodcuts, price 21*s.* (London: Cassell, Petter, and Galpin.)

THERE are two methods of reviewing a book, the ungracious and the gracious. One, and the easier, is to find all possible fault with it; to prove, at least to the critic's own satisfaction, how much better he could have written the book, if he too had had the time, and the money, and the will. As for the talent, the critic has that, as a matter of course; for is not a critic one who judges other men, and is therefore wiser than they? And as for the knowledge, that is not needed. He may acquire that in the very process of reviewing, from the book which he reviews. Thus, following nature in economising force as much as possible, he is at once learner and teacher; judge and—parasite? Taking another man's materials, he shows the world how much better a house he could have built with them; and so has the clear profit of all the author's work, his carrying of the bricks and mortar, even his planning the house, beside all the expenses incident thereto, at the cost on his own part of a few suggestions which he is not even at the trouble of seeing carried out. Thus he leaves the hapless man, who has tried to do something, instead of sitting still like the reviewer, and seeing others do it, to cry *Sic vos non vobis;* and after a few more attempts to write books, to give up in despair, and take to the more easy and profitable employment (at which every lad can now earn an honest penny), of showing how books should have been written.

But the other, or gracious method of reviewing a book, is to ascertain what the book is really worth, at least to the class for whom it is written; and if it be worth anything, to recommend it to them heartily; being sure that attractiveness is no test of value, and that there is no more utter fallacy than that good wine needs no bush.

Unfortunately, this gracious and hearty method of reviewing a book is not only difficult, being contrary to the affections and lusts of the animal within, who delights to bite and devour his kin, while he is indignant at the very notion of his ancestors having been cannibals: but it is also morally dangerous; for if the reviewer begins by being gracious and hearty, he may descend to kindness, even to indulgence. He may be to the author's "faults a little blind, and to his virtues very kind;" and so fall altogether from that boasted impartiality which surely portends detraction.

For the sake, therefore, of preserving the virtue of impartiality, it is most prudent for the reviewer to begin by complaining, and to say that this very beautiful book has certain defects, which he hopes may be amended in future editions (for he must be allowed to be gracious enough to hope for future editions); that several of the most important and novel illustrations have no authority appended; that the very clever drawing of the sea-lions has not only no authority, but no description or notice in the text; that some chapters are meagre, and some of the illustrations bad—for instance, the Holothurians, of which only two very poor and inaccurate cuts occur; that the large drawing of Cuttle-fish is also very bad and wrong; and that there are many misprints and misspellings (possibly mere faults of the printers, but still faults), such as *rostro* for rostrum, *Ottary* for Otary, *a* Poritidæ, *an* Alcyonideæ, &c., which must be corrected; and that, as a whole, the latter part of the book is inferior to the beginning. It may be, of course, that this is owing to the simple fact, too common among other classes besides publishers, that the money did not hold out; or that the book, if finished in the style in which it was begun, would have grown too big to be published at a paying price. But what has a reviewer to do with excuses and with mercy?

Having thus fulfilled his duty, he has something of a right to take his pleasure; and to say—Here is a really beautiful book. It is a pleasure to turn over the pictures; a pleasure to think that it will lie on many tables, teaching folk, especially young folk, a thousand things which those of the last generation did not learn, hard as they worked, each for himself alone, simply because the works which could teach them were not yet written; nay, the microscopes which could show the facts not yet made. The text is, as is to be expected from M. Moquin Tandon, brilliant, interesting, full of feeling for that wonderful and poetic element which runs through nature, and should therefore run through sound physical science. The illustrations are, on the whole, very good indeed; the large tinted plates altogether exquisite; notably one of the development of corals; and many of the cuts are not only accurate, but real works of art; for instance, a drawing

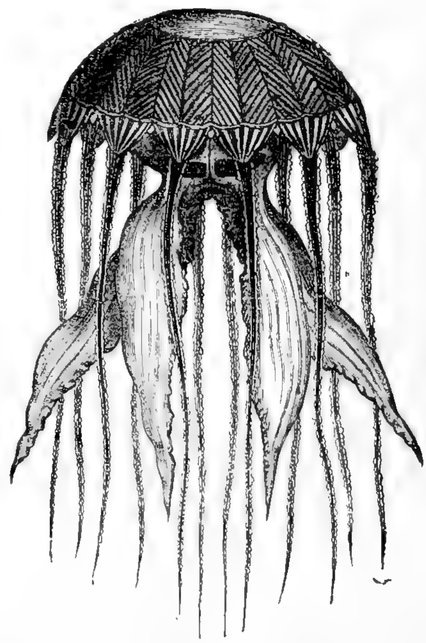
THE BEAUTIFUL-HAIRED MEDUSA (*Cyanæa euplocamia*)

seemingly from a photograph, of sponges, &c., on laminaria stems, and three drawings of medusæ, pp. 132-4, in which the grace and grandeur of the natural outlines has been excellently preserved.

Especially do the author, translator, and publishers deserve thanks for the mere number of the illustrations.

THE CROSS MEDUSA (*Rhizostoma cruciata*)

If the wonder of nature is ever to be got into the heads of the uneducated (rich or poor) it must be done, in the long run, through the eye. "Pictures," said certain men of old, "are the books of the unlearned;" and they used them with effect during the middle ages, to get into the heads of men wonders which—nineteen twentieths of them—never happened at all. Let Science, now her turn is come, use to the utmost of her resources, the same engine, to get into the heads of men—and of children from their earliest years—some of the wonders which are actually happening round them all day long. Let scientific men, therefore, welcome graciously this book, and all books of the kind, in spite of a few defects of haste or of insufficient knowledge. Let them recommend it to their friends—especially to those who have children. And if any shall raise the cry of "book-making," let them answer, "What else would you have?" In this age of "specialisation," when each minute branch of physical science requires a life-time of research, how are the many unscientific to be taught the vastness and beauty of Nature, save by book-makers; by those who take the results of other men's labour, and cast them together into a shape which the many will care to look at? Provided



THE MEDUSA OF GAUDICHAUD (*Chrysaora Gaudichaudii*)

they do not actually steal, allow them to borrow as freely as they will. What they borrow from the scientific writer, they will repay him a hundred-fold, in the form of pupils readers, and enlightened public opinion. Meanwhile, those who wish well to the cause of Truth, may trust that by every book of this kind one more human being will be awakened to the magnificence, as well as the importance, of facts; one more will be saved from the ancient empire of unreason; one more will be inclined to give rational glory to God, as he discovers how glorious His works are, even in the minutest polype; one more artist will discover, in his search for the beautiful, that the world contains a few objects quite as worthy of his pencil, as a Scotch fir-tree, or a country lane; and one school-boy, it may be, or even undergraduate, seeing this book in his sister's hands while he is at home for the vacation, will be led to inquire (not without reason) why he also is not taught something about these strange and beautiful works of God, and something of the science which investigates them, instead of the mispronounced Latin and Greek, in learning which (and most imperfectly) he spends the ten or twelve golden years of youth. He will receive for answer (or rather he will soon learn to answer himself) that those who have the monopoly of education know nothing of these matters, and therefore cannot teach them; while those who do know about them are not asked to teach them, because they will not pay in an examination. But that discovery may make him resolve, for the sake of his children or his younger brothers, to do what in him lies when he grows up, to alter radically the course of instruction now pursued in almost every boys' school in these islands; in which case this book, and others like it, will not have been published in vain.

C. KINGSLEY

BARFF'S HANDBOOK OF CHEMISTRY

An Introduction to Scientific Chemistry; designed for the use of Schools, and Candidates for University Matriculation Examinations. By F. S. Barff, M.A. Second Edition. Fcap. 8vo. pp. xv. and 315, with woodcuts, price 4*s.* (London: Groombridge.)

THE rapid progress of experimental discovery is in itself an obstacle to the elementary teaching of any scientific subject. Nowhere has the truth of this observation been more frequently attested than in chemistry, a science which, during the present century, has had a more brilliant, or at least a more active, career than any of its old companions. We cannot, therefore, be surprised that the superior attractions of research have so far had a depreciating influence on the dogmatic department of this study, that many chemical manuals are meagre, partial, or unsystematic. It is true that a large number of such books has appeared during the last few years, under the powerful stimulus of an increasing demand for chemical education; but their general character is such as we have assigned, and the composition of a treatise for the use of school-boys seems to have been in many cases shelved, as either too humble or too great a task for an author.

Such considerations induce us to welcome very cordially the little handbook which Mr. Barff has just republished. The first edition must be too well known, and too fresh in the memory of many of our readers to render any detailed reference to the present one necessary. The writer's efforts have evidently been directed towards attaining as much as possible of both clearness and brevity in exposition; but his tendency to avoid speculative assumptions is still more meritorious. No one is more sceptical than a boy; no one more difficult to convince by experiment of the truth of a theory. The teacher will therefore economise his time in the most useful manner by putting before his class only the simpler practical illustrations in which he knows he can succeed, and but a few of the most general and securely established laws. Hence Mr. Barff has boldly, but very judiciously, postponed the entire discussion of formulæ and symbols to the concluding portion of his work, using in its former part only absolute units of weight and measure—which, of course, have the advantage over the usual abstract numbers, that an audience can see and handle them. The nomenclature is that first systematised by Berzelius, and introduced into this country by Professor Williamson; it has also been adopted of late in the examinations of the University of London.

The method of imparting elementary instruction in chemistry is, as we have indicated, neither mature nor on the point of attainment. But whatever course may ultimately be decided upon, we can hardly doubt that it will include Mr. Barff's fundamental principle. Meanwhile this little volume, with its business-like spirit and undeniable accomplishment of its design, deserves the general and hearty commendation of teachers.

E. J. MILLS

OUR BOOK SHELF

Contribution to Climatology.—*Klimatologische Beiträge.* By Professor A. W. Dove. (Berlin, 1869.)

ISOTHERMAL Charts like those published by Professor Dove in 1864 derive their chief interest from the fact that they permit a birds'-eye view of the great climatological features of the globe, but they are of comparatively little value to the meteorologist, unless accompanied by the numerical data on which they are founded. These are now supplied by the publication of the present volume, which, however, contains also a great deal of matter of interest to the intellectual community generally. The introductory remarks to the tables on the climate of Western Europe, and on non-periodical meteorological phenomena, will show that the distinguished author has just claims to be considered the greatest master of meteorological generalisations.

B. L.

Wonders of Italian Art.—By Louis Viardot. Small 8vo. Pp. 257. Illustrated with photographs and engravings. (Sampson Low & Co.)

IF photographs were not children of the sun, and if artists were not sometimes—like Leonardo da Vinci—men of science, and would always work the better for a knowledge of it, and if scientific men were not among those who can most highly appreciate works of art, this book would hardly come within our programme. It is a beautiful book, full of beautiful photographs and engravings of the best and most typical pictures of the Italian school, and one altogether refreshing to look upon. We should also add, that it is translated from the "Bibliothèque des Merveilles," which contains so many works on science.

Astronomical Publications.—1. *Astronomische Mittheilungen von der Königlischen Sternwarte zu Göttingen.* (Göttingen, 1869.) 2. *Sammlung von Hilfstafeln der Berliner Sternwarte.* By W. Foerster. (Berlin, 1869.)

THE first publication is an account of some recent astronomical labours at the Observatory in Göttingen, and contains the results of observations with the meridian circle in zone 0° and 1°, made in accordance with the well-known scheme of a zone revision so successfully initiated and established by English and Continental astronomers. The volume, which deserves in every respect the special attention of star observers, contains the mean places of stars up to the ninth magnitude, reduced to 1875·0. A new method of calculating the determinations of time, originally proposed by Gauss, has been for the first time made use of by the observers. It is shown at page ix. of the Introduction, and will be found of the highest merit.

The Berlin publication contains a set of tables for the routine business of the Observatory. Although calculated with reference to the local circumstances of the Berlin establishment, they are likely to be instructive elsewhere, their arrangement being extremely compact and at the same time lucid.

B. L.

The Half-crown Atlas of Physical Geography. By Keith Johnston, jun. 31 maps, printed in colours. Small 8vo. (Edinburgh, Johnston.)

THIS atlas astonishes and delights us. For two shillings and sixpence we at last get beautifully finished maps, showing the land and water hemispheres, and the lands which are blessed with an antipodes; a perspectic view of the globe; physical maps of the continents, Australasia, British Isles, and the Holy Land, a geological map of the British Isles, maps of ocean and river systems, ocean basins, winds and storms, annual isothermal lines, and range of temperature, distribution of earthquakes and volcanoes; the geographical distribution of useful plants and species, the chief animals, and varieties of man himself. There are, moreover, notes as to the preparation of the atlas, and an analytical index. We warmly congratulate Messrs. Johnstons on their last achievement, and advise everybody to buy the atlas.

Cassell's Technical Manuals.—1. Linear Drawing. 2. Projection. 3. Building Construction. By Ellis A. Davidson. Price 2*s*. each. (London: Cassell, Petter, & Galpin.)

THESE little books are intended to promote the technical education of artisans, and seem to be well-adapted to facilitate the work of teachers and learners. The manual of Linear Drawing shows the application of practical geometry to trade and manufactures, and has been appropriately chosen as the first volume of a technical series for craftsmen. The methods of constructing geometrical figures are given without the mathematical proofs which usually accompany such problems. The application of some of the figures to decorative and mechanical work is illustrated in diagrams of the trefoil, quatrefoil, toothed wheel, ellipse, &c. Accuracy is persistently inculcated, and all the figures are admirably executed. The manual of Projection leads the student many steps further, and treats of the drawing of plans, elevations, and sections of solids. The chapter on isometrical projection explains that system of drawing in a clear and concise manner. In some of the more elaborate figures fewer lines of construction might have been used with advantage. The observations on drawing instruments, and their use, are thoroughly practical. The third treatise elucidates the principles of Building Construction, and gives some useful hints on architectural drawing. It is profusely illustrated with diagrams; these are generally good, but the minor details of a few need correction. C. W. W.

Picture Natural History. (London: Cassell, Petter, and Galpin.)

WE have submitted this volume to an abler critic than ourselves—to a little boy. He is delighted with the pictures, and interested in the text. We should like to give it to every little boy and girl we know.

Tommy Try, and what he did in Science. By C. O. G. Napier (of Merchiston), F.G.S. Pp. 302, with 46 Illustrations, by J. D. Cooper, and others. (Chapman & Hall.)

A BOOK for boys, in which science and anecdote chase each other through a pleasant narrative, until Tommy Try takes to consulting phrenologists, and then, fortunately for his young readers, brings his memoirs to a close.

THE SUEZ CANAL

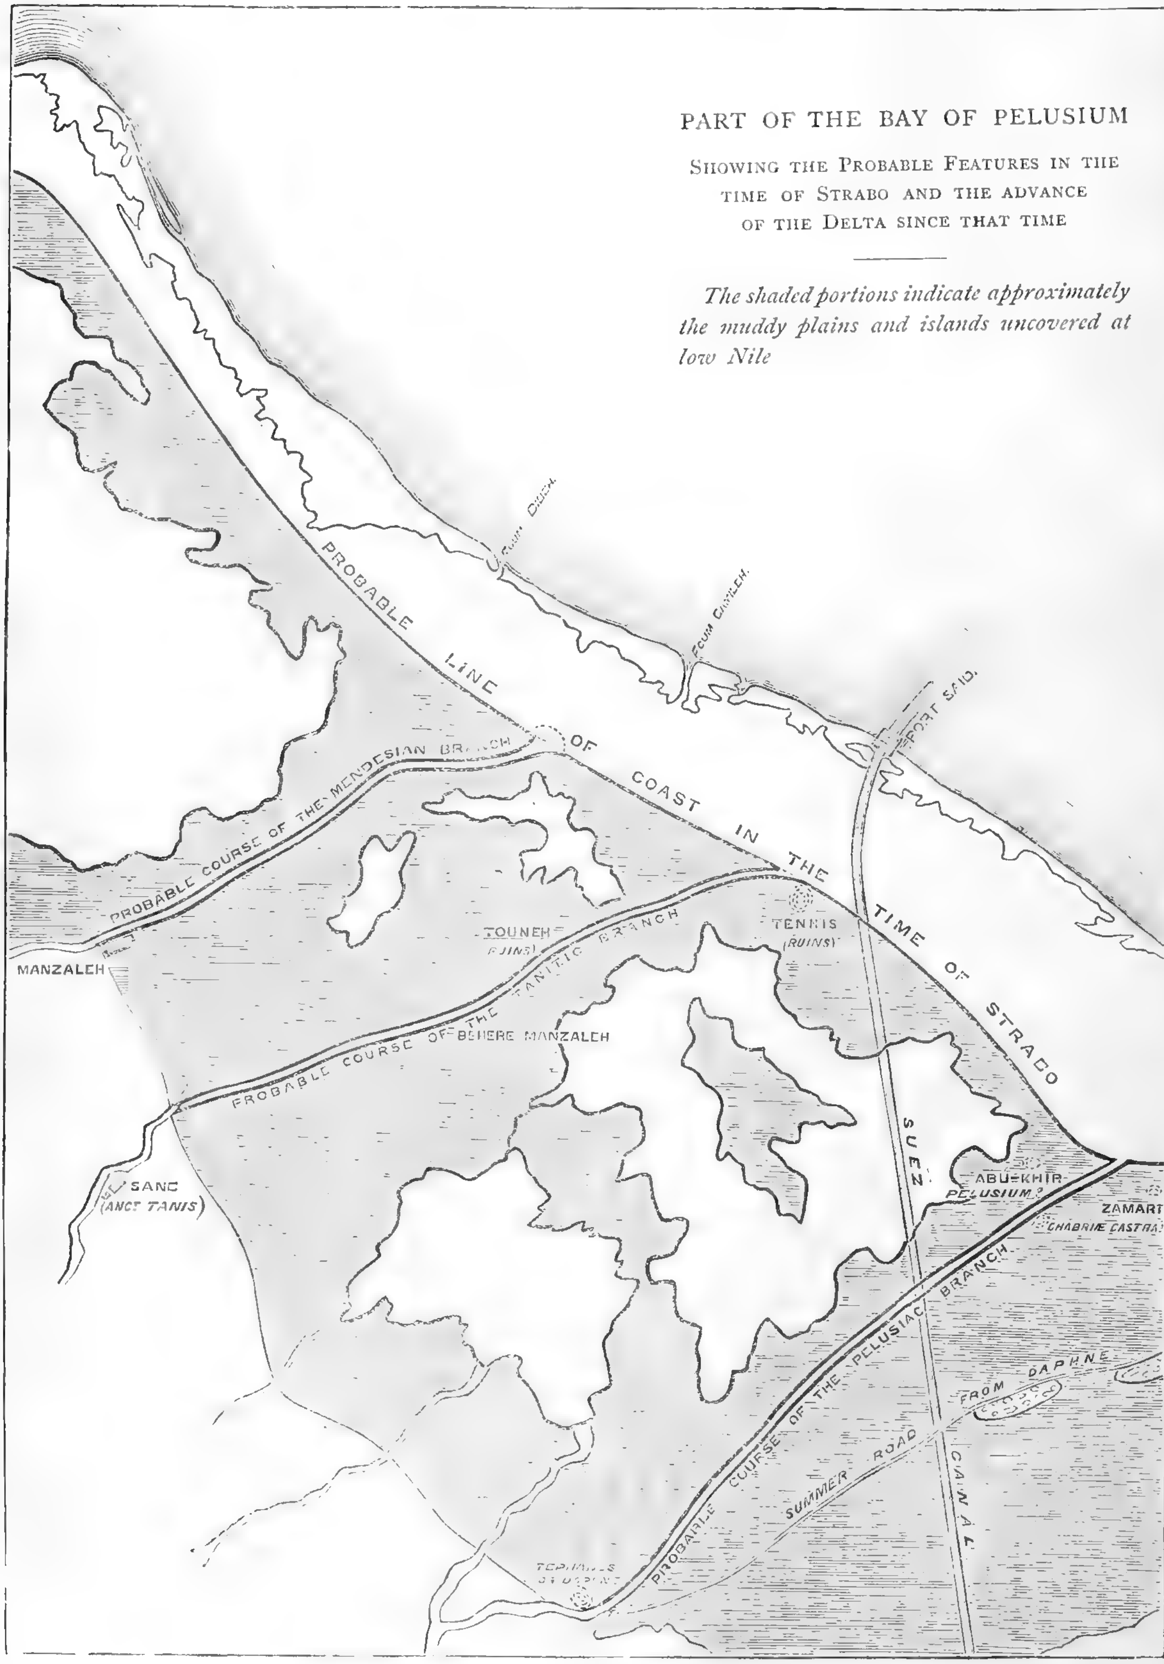
IF all went well, and we hope it did, yesterday witnessed a grand gathering on the sandy shores of a dreary bay in the Midland Sea—that sea around which so much of history has been enacted, and in whose annals the gathering in question will not be the least noteworthy incident. The Suez Canal—that problem of many centuries—is to be opened in presence of emperors, kings, princes, and potentates; of eminent engineers, famous warriors, and distinguished *savants* invited from the East and from the West; and while the ceremonial lasts the very dreariest of the dreary wastes that here and there border the blue waters of the Mediterranean will be animated by a brilliant throng and the sound of music; and speeches will be made and healths will be drunk, and all present will join in wishing success to the memorable enterprise, which, for a time, is to furnish to Arab story-tellers and Frankish newsmongers a topic to talk about.

Dreary as the region is, it has a history. There marched with invading armies the kings whose names are recorded in Scripture; there Artaxerxes was stayed in his victorious advance by the siege of Pelusium; there are yet to be seen relics of cities and towns named in the "Itinerary" of Antoninus; there Titus marched to the siege of Jerusalem; there Baldwin and his Crusaders took the city of Pharamia: the actors in these and other exploits never dreaming that the sands of the desert, drifted by the winds and by the stream of the Nile, would so bury and alter the surface of the land, that after generations should be puzzled to identify its historical localities.

The question of a canal dates from a very early period. In high floods the waters of the Nile spread to within two or three miles of the Red Sea, which would suggest the idea of a permanent communication between the river and the great Arabian Gulf. This communication was actually established, as is said, under Ptolemy Philadelphus; but of course it fell into neglect, and was buried under the drifting sands, until one of the caliphs had it cleared out, after which there was a navigable canal between the Nile and the Red Sea for more than a hundred years. Then it was again lost, and so completely that its ever having existed became matter of doubt and dispute.

But the main project was a ship canal across the isthmus. There is some tradition that Alexander consulted with his engineer officers as to its feasibility, and that they reported against it on account of the difficulty in preventing the mouth of the canal from silting up. In a later age Sultan Selim, who had been baffled in his scheme for a canal to connect the Don and Volga, resolved on cutting one from Pelusium to Suez; and he took an important step towards accomplishing his purpose, for he conquered the country all across, and made his name a terror to the Arabs. But he did not live to cut the canal. The first Napoleon revived the project, and ordered a survey, during which the long-buried remains of the canal above-mentioned were discovered, and the question as to its having existed was settled. From that time the question of a ship-canal became a standing topic, enlisting divers opinions, among which were some to the effect that the project was simply impossible, because, as the level of the Red Sea was so much higher than that of the Mediterranean, the swift current in one direction would prevent navigation.

During this time of debate, Captain Spratt of the Royal Navy was sent, with the ship *Medina*, to make a survey along the shores of Egypt and of the Isthmus, of which an account was published by the Admiralty in 1859, entitled, "An Investigation of the Effect of the prevailing Wave Influence on the Nile's Deposits;" and this was followed by "A Dissertation on the True Position of Pelusium and Farama." Beginning at the western extremity of the Egyptian coast, Captain Spratt found that the Nile there exerted no influence, but that, owing to the prevalent north-westerly and westerly winds, the deposits brought down by the Nile were drifted to the eastward in prodigious quantity, even to the shores of Syria. This was no hasty conclusion: by a careful series of soundings and dredgings, Captain Spratt determined the identity of the sand along the sea bottom, within a given distance of the shore, with that of the deserts through which the Nile flows. Farther out to sea the sand was coralline, and of an entirely different character, while the Nile drift is made up of quartzose sand, with fine mud and particles of mica. The verifications in this particular were too



PART OF THE BAY OF PELUSIUM

SHOWING THE PROBABLE FEATURES IN THE TIME OF STRABO AND THE ADVANCE OF THE DELTA SINCE THAT TIME

The shaded portions indicate approximately the muddy plains and islands uncovered at low Nile numerous and too exact to leave room for doubt. "By this means," writes Captain Spratt, "I was enabled to trace the extent of the Nile's influence both directly off the coast and along it, as well as to ascertain the large quantity of sand—pure silicious sand—it must annually bring to the sea; and to an amount which far exceeded my expectations and experience in respect to other rivers, particularly that of the Danube, which, in comparison, brings a very much less proportion of sand to mud. The Danube sand, also, is of the finest quality. The Nile sand, on the contrary, is much coarser generally, and forms sandbanks off the coast that are composed of quartzose sand nearly as large as mustard seed."

The quantity of solid matter brought down by the Nile when in flood is prodigious, and precisely at this season—that is, for three or four months—the north-west winds blow strongest. Indeed, if the wind did not blow with the violence of a monsoon it would be impossible for sailing-vessels to navigate the river during the time of its rise. The suspended matter is consequently driven to the eastward along the coast, and there accumulating forms dunes or sandhills, which shift their position with every gale, "burying at times the huts of the coastguard men." The hollows between the dunes are cultivated by the Arabs, but the plots must be protected by screens of reeds, against which the sand accumulates by repetition, until in some instances the hill is a hundred feet in height. Captain Spratt here remarks: "The best efforts of a population of several thousand Arabs, who inhabit the villages along this strip of land, fail in permanently fixing these dunes. For as the sea continually reaccumulates the sand upon the beach, onward it moves, in spite of those efforts, and the rate of progress may be imagined when I state that a mosque near Brulos has in about twelve months been nearly buried in one of the dunes" advancing from the westward. "And as the coarse sand of which these hills are composed is not distinguishable in differing from the sands of the desert near the Pyramids, or that on the route to Suez, they must undoubtedly be all the gifts of the Nile."

Besides coarse sand the Nile carries down fragments of brick, pottery, and other heavy substances, which are also drifted along the coast by the combined action of wind and current. When the wind blows its strongest the coastguard men say they cannot walk against it. To test these facts, Captain Spratt one day landed eleven bags of ashes and clinkers, five of the bags containing pure clinkers, the largest of which weighed from four to five pounds. The whole were laid in a heap just above the water's edge, and left to the care of wind and sea. Twelve days later, when the party returned, not a vestige of the heap, which had weighed nearly two tons, was to be seen. The shore was examined towards the quarter from which the wind blew, but without result; while in the other direction, that of the prevailing wave movement, clinkers weighing about two ounces were found dispersed to a distance of fully 1,500 yards, one of $3\frac{1}{2}$ pounds was picked up at 240 yards, and others from 4 to 8 ounces at from 600 to 700 yards. The greater portion had, however, been buried by the movement of the sand. "Thus this evidence," writes Captain Spratt, "of the movement of the beach in only twelve days, in the month of May, during which there was but one strong westerly breeze and several fresh easterly breezes, is a positive evidence of the great easterly movement of the shore and littoral shallows along this coast, but which, during a succession of winter gales, and during the prevailing north-west breezes at the period of high Nile, must cause a continuous progression of an immense quantity of the sands and matter carried out by the turbid river."

We quote another passage bearing on this point. The captain was walking along the coast for the purpose of observation, from the beacon marking the site of Port Saïd, to the head of the bay of Tineh, when he found a great quantity of broken pottery, broken jars, ancient and modern, and broken bricks scattered on the shore, at the highest and lowest surf margin. "On discovering them in such quantity," he continues, "I was naturally anxious to trace out their origin, thinking they must have come from some adjacent ruin. But I found eventually that they had come wholly from the mouths of the Nile, and that they were the positive *débris* from the towns situated on the banks of the river, and brought out by the strength of the current at high Nile, but then dispersed along the coast to the eastward by its littoral currents and prevailing ground swell."

It would be easy to multiply facts, if further evidence were wanted, that the Nile is no exception in the great transforming powers of Nature, washing down the dry land into the sea, and forming there beneath and on the margin of the waves new continents and islands. The Mississippi, the Ganges, the Yang-tse-Kiang, and other rivers of the great continents, carry down millions of tons of solid matter every year. The North Sea is gradually being silted up by the rivers of Belgium, Holland, and the British islands. At the mouth of the Ebro, on the northern side of the Mediterranean, the deposits brought down by the river are in course of reclamation by an eminent English engineer. Hence we need not feel surprise that the Nile—one of the greatest of rivers—has during long ages wrought great changes on the southern shores of the same sea. In the face of facts such as are above adduced, a government or a nation might well be justified in believing the project of a harbour and canal on the Bay of Pelusium to be, if not impossible of execution, at least unprofitable. Places which were on the shore when Strabo wrote are now from four to six miles inland, as is shown on the accompanying map, reduced from that published with Captain Spratt's report; and this modifying action is still going on.

Since the Suez canal was first projected engineering science has advanced; and though the sands will accumulate at Port Saïd as from of old, the piers and breakwaters will be periodically lengthened, made to stretch further and further into the sea, while powerful steam-dredges will scrape away the sand from the mouth of the harbour. Whether heavy gales will effect any more serious choking of the approaches, or drift tons of blowing sand into the canal itself remains to be seen. But while the world is greeting, and worthily greeting, the great work as a triumph of engineering skill, it may be well, at the same time, to bestow a little thought on the facts and conclusions here brought under notice, which in the pre-scientific age rendered man's contests against the works of the winds and sea perfectly hopeless.

MEETING OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

IN the last number of *Silliman's Journal* is an account of this year's meeting of the American Association, held at Salem, under the presidency of Mr. J. M. Foster, of Chicago, which seems to have passed off as pleasantly and usefully as did our own at Exeter. Over one hundred and fifty new members were elected. The number of communications entered upon the daily programmes of the Standing Committee was about one hundred and fifty. The range of these papers was considerable, and it was found expedient to have sub-sections on Archæology and Microscopy, to facilitate the disposal of papers which could not be reached in the other sections.

The then recent total eclipse of the sun was naturally a prominent subject of interest; the astronomers being present in considerable force.

The dedication of the Peabody Academy of Science was an occasion worthy to occupy the attention of the Association at its opening session. A few notes on this Academy will be welcome to many readers. The Institution was founded at Salem in the year 1867, by the munificence of George Peabody, with the design of promoting the study of science in his native county of Essex. The first Annual Report of the Trustees of this Academy, made in January, 1869, shows that it is already fully organized, with an able corps of officers and a well-ordered museum, library, &c., and the activity of its Director and Curators is evident not only in the extent and fine condition of the collections, but in the zeal and ability with which the various publications of the Academy are conducted. Advantage was taken of the present occasion to make the formal transfer of the building of the Museum to the Trustees, and its delivery and acceptance by the Director, Mr. F. W. Putnam. In an eloquent address the President of the Academy, Mr. William C. Endicott, gave the history of the Museum from its foundation, in 1801, as the East India Marine Hall, to its purchase and reorganization in its present form. The Essex Institute, which is well known by its Proceedings, Bulletin, and Historical Collections, is now incorporated with the Peabody Academy of Science.

The address of Dr. B. A. Gould, the retiring President of the Association, dealt with the Position of Men of Science in America.

Everything which a hearty good will and an intelligent appreciation of science could do was done to promote the happiness and forward the plans of the Association and its members, alike by the city authorities of Salem, the various scientific bodies, and private individuals. We confess we should have been glad to learn that our English scientific men had been represented at the meeting, as America was represented at Exeter by Professors Newton and Lynan.

The Association will meet next year at Troy, New York, under the presidency of Professor Chauvenet, of St. Louis University.

The following, which were among the papers read at the meeting, will give an idea, not only of the great scientific importance of the congress, but of the direction in which many of the most eminent scientific men in America are working at the present time :—

SECTION A. *Mathematics, Physics, and Chemistry.*—On the Total Eclipse of Aug. 1869; B. Pierce.—On Quintuple Algebra; B. Pierce.—Determination of the Mechanical Equivalent of Heat, by means of the modern ice and cooling machines ; P. H. Van der Weyde.—The Spectral Bands considered as harmonics of one or more fundamental longer waves, lying beyond in the invisible caloric rays ; P. H. Van der Weyde.—On the audible transmission of musical melodies by means of the Electric Telegraph; P. H. Van der Weyde.—Electricity not a self-existent fluid, but a mode of motion of matter ; P. H. Van der Weyde.—Flame Temperatures, in their relations to compositions and luminosity ; B. Silliman and H. Wurtz. — On the relation between the Intensity of Light produced by the Combustion of Illuminating Gas and the Volume of Gas consumed; B. Silliman. —Causes of the Failure of Lightning Rods ; J. Bushee.—Conditions of a perfect Lightning Rod ; J. Bushee.—The Laws of the Deflection of Beams tested by experiment; W. A. Norton.—The physical theory of the Principle of the Lever; W. A. Norton. —Planetary Influence on Rainfall and Temperature ; P. E. Chase. —The use of the Thermometer to determine the period of Solar Rotation ; P. E. Chase.—Some observations on the Solar Eclipse at Montreal, by Dr. C. Smallwood, with Photographs taken by Wm. Notman. Communicated by B. Edwards.—A new method of observing Contacts at a Solar Eclipse by the Spectroscope ; C. A. Young. — The Spectrum of the Solar Prominences and Corona, as observed at Burlington, Iowa, in the last Solar Eclipse, and the coincidence between the bright lines of Corona Spectrum and those of the Spectrum of the Aurora Borealis ; C. A. Young.—The Solar Eclipse, and the Outlines of the Corona as observed at Des Moins ; T. Bassnett. —Remarkable case of freezing Fresh-water Pipes in Salt-water; W. W. Wheilden.—The Thermodynamics of Waterfalls ; A. M. Mayer.—On some further evidence of the existence of a System of Arctic Winds; J. H. Coffin.—The present condition of Lighthouse Illumination in the United States ; J. Henry.—A new method of rendering the Needle of a Galvanometer definitely astatic ; M. G. Farmer.—On an improved construction of the Holtz Electrical Machine, adapted for the analysis of the phenomena of this variety of machine, and for Class-room use ; R. E. Rogers.

SECTION B. *Geology and Natural History.*—Comparison of the Coral Faunæ of the Atlantic and Pacific Coasts of the Isthmus of Darien, as bearing on the supposed former connection between the two Oceans; A. E. Verrill.— On certain Peculiarities in the distribution of Marine Life on the Sea-bottom of the Bay of Fundy ; A. E. Verrill.—American Phyllopod Crustacea ; A. E. Verrill.—The Homologies and general structural relations of the Polyzoa ; A. Hyatt.—Observations on a new genus of Polyzoa ; A. Hyatt.—New Species of Fishes obtained by Prof. Orton in the valleys of the Maranon and Napo ; T. Gill. —Notice of some new Fossil Plants from Gaspé, discovered by Prof. J. W. Dawson ; J. S. Newberry.—On some points in the Geology of North Carolina ; W. C. Kerr.—Preliminary notice of the Lamellibranchiates of the Upper Helderberg, Hamilton and Chemung Groups ; J. Hall. — On the Classification of the Diurnal Lepidoptera ; S. H. Scudder.—The Morphology of the Abdominal Appendages of Butterflies ; S. H. Scudder.—The value of the characters drawn from the external Armature of Lepidopterous Larvæ ; S. H. Scudder.—A classification of the Eggs of Butterflies ; S. H. Scudder.—Two new genera of Extinct Cetacea ; E. D. Cope.—Discovery of the Ammonoosuc Gold Field ; H. Wurtz.—Note upon the Palæotrochis ; H. Wurtz.—Notices of some new Tertiary and Cretaceous Fishes ; O. C. Marsh.—Metamorphosis of Siredon into Amblystoma ; O. C. Marsh.—On some new Mosasauroid Reptiles from the Greensand of New Jersey ; O. C. Marsh.—Homologies of the Palæchinidæ ; Alex. E. R. Agassiz.—On Surface Changes in Maine indicating the length of time since the close of the Quarternary Period ; N. T. True.—Compression as an agent in Geological Metamorphism, with illustrations of distorted pebbles in conglomerates ; G. L. Vose.—On the Plasticity of Pebbles and Rocks ; W. P. Blake.—Flora and Fauna of the Fresh-water Tertiaries of Oregon and Idaho ; J. S. Newberry.—On new species of Fishes obtained by Prof. Orton in the Valleys of the Maranon and Napo ; T. Gill.

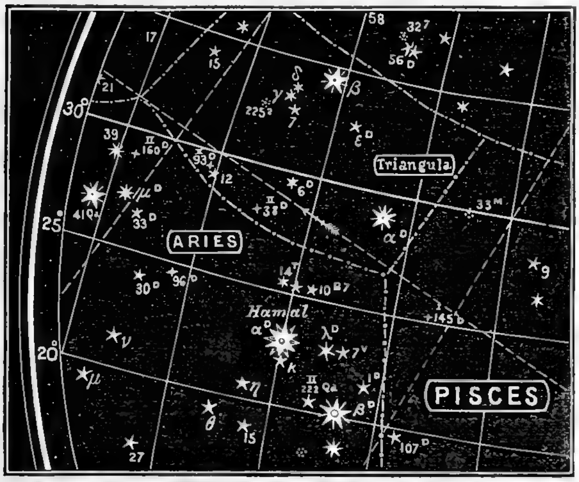
SUB-SECTION C. *Archæology and Ethnology.*—Conjectural explanation of Uses of the Embankments of the Mound Builders ; L. H. Morgan.—Discovery of the Remains of the Horse among the Ancient Ruins of Central America ; O. C. Marsh.—Exhibition of a few interesting Implements collected by R. W. Haskins from Indian Graves on the banks of the Ohio, with special reference to the boring of holes in stone implements; F. W. Putnam.

NEW STAR-ATLAS

MR. R. A. PROCTOR has planned a star-atlas on a plan which presents several advantages. The celestial sphere is to be divided according to this plan into twelve equal parts, each pentagonal in shape ; but, each map being made circular, there is a slight overlapping, which prevents any star-group from being broken off at the edge of a map, as in all the arrangements hitherto adopted. Owing to the equality of the maps and the choice of a central projection (the equidistant) the distortion is reduced to a minimum. In fact, for the first time in the history of star-mapping, a plan is adopted by which, with a moderate number of maps, there is no appreciable distortion or scale-variation. The woodcut which gives (on a reduced scale and with inverted colours) a portion of Map 2 of the series (where it overlaps Map 4), exhibits some of the principal peculiarities of the new scheme. It will be noticed that though this portion belongs to the outer portion of the map (where the distortion is greatest) the figures between the parallels and meridians are of their proper shape. The arrow indicating precession in direction and magnitude (for 100 years) is a novel and very simple mode of exhibiting this important relation. The way in which the constellation-names are introduced is also new, and seems preferable to the old arrangement, in which the name straggling over the whole constellation at once confused the star-grouping, and was itself almost illegible unless printed in very large letters. The figure also includes instances of the mode of marking double, triple, and multiple stars, binaries (known or suspected), variables, Messier's nebulæ, Sir W. Herschel's classification of his nebulæ, and so on.

All stars in the B.A. Catalogue down to the sixth magnitude inclusive are to be introduced, besides all the objects in the Bedford Catalogue, Messier's nebulæ, about 100 variables, red stars, and other objects of interest (in all about 1,500 objects). The scale of the maps is to be that of a 20-inch globe, and each map will be rather more than thirteen inches in diameter.

Mr. Proctor's series of gnomonic maps, in which the sphere is divided into the same set of pentagons, which



are arranged into two sets of six (namely, five northern equatorial maps around the north polar map, and five southern pentagons similarly arranged around the south polar map) will be added as index maps. As in these maps the constellation figures (coloured) are introduced, all necessity of adding these figures to the large maps is avoided, and so the clearness of the maps is much increased.

A letter-press introduction, with a list of star-names, will add to the completeness of the maps. Mr. Brothers, of Manchester, will photo-lithograph the maps if it should appear from the receipt (by him) of a sufficient number of names as subscribers, that the scheme is approved of by astronomers. He will supply to subscribers a specimen of Map 2, which alone is yet completed.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents.*]

Personal Equation of Astronomical Observers

CAN any of your readers inform me whether an attempt has hitherto been made to determine the absolute Personal Equation of Astronomical Observers? The most important of all astronomical observations consists in noting the time of passage of a star across the wires of a transit instrument; but it is found that no two observers exactly agree in the time assigned to the passage. From peculiar habit or bodily constitution some observers almost invariably register the passage of a star a fraction of a second before other observers. From the Introduction to the volumes of Greenwich Observations, we learn that it is the practice at the national Observatory to compare the observations of the junior observers with those of the principal observer, and to assume that the latter is correct. All the observations are thus brought into consistency with each other; but it is not known, I believe, whether all the time observations may not be a fraction of a second too soon or too late.

Cannot this question be determined experimentally in a very simple manner? Imagine an artificial star, formed by a minute electric spark, placed at a considerable distance, say three miles, and made to move across the field of a transit instrument at a rate not very different from the average apparent rate of stars observed (say nine inches per second): very simple mechanism might be devised to register upon the chronograph of the observatory the exact moment at which the star is absolutely upon each of the cross wires of the telescope. At the same time the observer, whose error is to be determined, should endeavour to record in the ordinary way the passage of the star, and the difference of time, as shown on the chronograph, would give the required error. Every observer might thus be put through a kind of exercise, which would inevitably show the degree of his proficiency, or detect any change in his habits of observation.

I need hardly say, that however small may be the remaining personal error unallowed for in the Greenwich observations, the time may come when the determination of some most important astronomical question may depend upon that quantity. And though those observations may at any one time be rendered perfectly consistent *inter se*, by reference to one observer's result, yet they cannot be strictly comparable with the observations of other observatories, or those of the same observatory at distant periods of time, because the one same observer would not be present to give the assumed standard. It might be of considerable importance, therefore, to establish a mechanical criterion of the accuracy of time observations which could be appealed to at any observatory, and at any future time. I have not been able to learn that such an experiment has hitherto been tried.

J.

The Fertilisation of Winter-flowering Plants

WILL you permit me to add a few words to Mr. Bennett's letter, published at p. 58 of your last number? I did not cover up the *Lamium* with a bell-glass, but with what is called by ladies, "net." During the last twenty years I have followed this plan, and have fertilised thousands of flowers thus covered up, but have never perceived that their fertility was in the least injured. I make this statement in case anyone should be induced to use a bell-glass, which I believe to be injurious from the moisture of the contained air. Nevertheless, I have occasionally placed flowers, which grew high up, within small wide-mouthed bottles, and have obtained good seed from them. With respect to the *Vinca*, I suppose that Mr. Bennett intended to express that pollen had actually fallen, without the aid of insects, on the stigmatic surface, and had emitted tubes. As far as the mere opening of the anthers in the bud is concerned, I feel convinced from repeated observations that this is a most fallacious indication of self-fertilisation. As Mr. Bennett asks about the fertilisation of Grasses, I may add that Signor Delpino, of Florence, will soon publish some novel and very curious observations on this subject, of which he has given me an account in a letter, and which I am glad to say are far from being opposed to the very general law that distinct individual plants must be occasionally crossed.

CHARLES DARWIN

Down, Beckenham, Kent, Nov. 13

Elimination of Alcohol

ALLOW me to remark on a statement made in one of the chemical notes of last week's NATURE.

A new test for alcohol discovered by M. Lieben is there described, and its alleged value in solving an important physiological problem is dwelt upon. Now the real course of events has been as follows:—Since the year 1860, when MM. Lallemand, Duroy, and Perrin published their researches on alcohol and anæsthetics, the old belief in the combustion of alcohol within the organism has been almost entirely upset; and it was supposed that this substance was entirely eliminated without change. Dr. Anstie was, I believe, the first who publicly criticised the conclusions of these physiologists, and showed, by a number of experiments, that a small proportion only of the alcohol introduced is excreted by the kidneys. [See Dr. Anstie, "Stimulants and Narcotics," Macmillan, 1864; also further researches recorded in his Lectures on Acute Diseases at the College of Physicians, *Lancet*, 1867, vol. ii.]

The question was next taken up by Dr. Thudichum, who estimated the amount of alcohol excreted by a number of men after they had taken a considerable quantity of wine, and proved it to be only one-half per cent. of the total amount swallowed. Finally, the writer of this, during 1866 and 1867, made numerous experiments in the same direction. In these, not only was it shown that alcohol can be detected in the urine secreted during several hours after the dose had been taken, but it was also quantitatively proved that the total proportion eliminated was an excessively small fraction of what was taken into the body. This was demonstrated both in the case of healthy men, and in that of persons suffering from disease. [See Tenth Report of the Medical Officer of the Privy Council, p. 288.]

Moreover, unknown to either of the above observers, M. Schulinus of Dorpat, in 1866, made elaborate experiments on animals, which also showed conclusively (1) that elimination of alcohol does take place, and (2) that it only represents a fractional part of the alcohol taken. [Archiv. f. Heilkunde, 1866.]

However delicate and useful, therefore, M. Lieben's test may be in itself, it was not needed to decide this question, which was already settled. A. DUPRÉ, Ph.D.

Laboratory, Westminster Hospital, Nov. 15

NOTES

THE Royal Society commences another session to-night. The communication of the results of the recent dredging expedition in the *Porcupine* will most probably take up the whole of the evening.

THE great "Catalogue of Scientific Papers compiled and published by the Royal Society," has now reached its third volume; a fact which we have much pleasure in announcing. In this the names of authors are carried on from GRE to LEZ inclusive, so that the compilers are nearly half-way through the alphabet. We congratulate them on their good progress, and can promise them the cordial appreciation of scientific men all over the world, to whom the work will prove of inestimable value. Does a mathematician wish to know how many mathematical papers have been written by Grunert, the well-known editor of the "Archiv," he turns to this volume, and finds 343. Guérin Méneville, the naturalist, figures for 326; Hagen, entomologist, for 102; the veteran Haidinger has 286 on minerals and meteorites; while Henwood, a Cornish celebrity, shows 55 papers on geological and mining subjects; and Heer, of Zurich, to whom we are indebted for admirable descriptions of fossil flora of the primeval world, numbers 46; Sir William Hamilton heads a list of 69 papers; Hansen, 103, probing deep into astronomy; Hansteen, the Norwegian, who lives to see in Sir Edward Sabine's researches, a grand outcome of his own early investigations of terrestrial magnetism, has 141 papers; Dr. Hooker appears for 58 papers; his late father for 72; and the late W. Hopkins, who did so much in mathematical geology, for 33. Dr. Hofmann, the eminent chemist, has made himself responsible for 156 papers; Mr. Lassell for 66, and Leverrier for 88. Kummer, recently elected a foreign member of the Royal Society, is down for 51; Leuckhart for 64; the indefatigable Isaac Lea, of Philadelphia, for 106, mostly about shells; and Lamont, of Munich, for 90, on magnetism, meteorology, and various questions in physical astronomy. From this brief selection our readers will see what a rich fund of scientific information has been prepared for their use by the Royal Society.

AMONG the recently published state papers of the American Government, is the annual report of the president of the National Academy of Sciences, from which we make the following extracts. It will be seen that in America there is no mistake about what is considered to be the duty of the Government in regard to scientific research—we wish we could say as much for England:—"The members of the Academy consist principally of professors in our colleges, and a few officers of the army and navy, who, from their social position and moral character generally, have the confidence of the public in a degree surpassed by no other class of the community. They are, however, generally men of limited means, receiving no pecuniary reward for their discoveries, and by law allowed nothing for their labours in the Academy, and who can ill afford the expense of assembling, from a distance, in the city of Washington. A small sum appropriated by Congress for the expense of their annual meetings, by which a full attendance could be secured, would be money well bestowed. It would stimulate higher researches, elevate the character of the association, and be productive of more valuable assistance to the Government. I feel myself more at liberty to urge the claims of the Academy, inasmuch as its members generally, including myself, took no step towards its establishment. Indeed, I must confess that I had no idea that the national legislature, amid the absorbing and responsible duties connected with an intestine war, which threatened the very existence of the Union, would pause in its deliberations to consider such a proposition. But Congress, having expressed its sense of the importance of an organisation of this kind, the members designated accepted in good faith the appointment, and have since endeavoured zealously to discharge the obligations thus devolved upon them. *It is now the duty of Congress to do its part, by furnishing the means to enable the Academy to fulfil its mission with credit to itself and the nation.*"

THE Minister of Public Instruction has given orders for the construction of an Agricultural Map of France, on a novel plan. It will be built up of specimens of the various soils, arranged according to locality.

FROM accounts of the last meetings of the Wellington Philosophical Society and New Zealand Institute which have reached us, it is clear that good scientific work is being done at our antipodes, much of it in Dr. Hector's laboratory. The most interesting result recently obtained is the isolation of the poisonous substance in the Tutu plant. Many experiments made for this purpose during the last six years, both in the laboratory of the Geological Survey and by chemists in Great Britain, failed to discover the poisonous ingredient of the plant. A short time ago, Mr. Henry Travers collected for the Museum a large quantity of ripe seeds of the Tutu (*Coriaria ruscifolia*), and on these Mr. Skey has recently experimented. He has discovered the poison to be a greenish oil, unaffected by, and insoluble in, water and mineral acids, but soluble in acetic acid, ether, alcohol, and chloroform. This oil is combined with a red-coloured resin, which is insoluble in ether, by removing which the poisonous oil was obtained in a pure state. The quantity of the poison contained in the seed is 12 per cent. of the weight. A similar oil has been detected by Mr. Skey to be the active poisonous element in the Karaka seed (*Corynocarpus lævigata*), which will account for its having hitherto escaped detection; and he suggests that the discovery might lead to the detection of the active principle of many poisonous European plants that have hitherto eluded research.

ANOTHER item of New Zealand news is that the result of all Dr. Hector's investigations into the geology of the islands is, that New Zealand must be considered as, on the whole, well supplied with mineral fuel. The most valuable description of coal is certainly confined to limited and not very accessible areas; but still there is nothing to prevent their being profitably worked for the supply of the steam service. The great point for congratulation, however, is, that throughout almost every part of the islands, coal of a practically useful description is to be found within a short distance.

WE are glad to see that the Essex Institute—not our Essex, but the American one—is extending its sphere of action by issuing a Bulletin in addition to their ordinary proceedings. The Bulletin is intended to give to the public such portions of communications made to the Institute at its semi-monthly and other public meetings, as are of popular interest. A brief summary of all the proceedings at each meeting will be given, which will contain the titles of all written or oral communications, and the names of their authors. A small space in each number will be used to announce the recent correspondence, and donations to the library and museum, and to state deficiencies existing in the collections, and the methods in which its friends may best aid in rendering them more complete. There will also be inserted a list of some of the duplicate volumes, pamphlets, newspapers, &c., in the library, which will be offered for exchange or sale. It is expected that the variety and interesting character of the communications this volume will contain, will make it a favourite with the public, while its low price will bring it within the means of all. The Bulletin can be obtained of Messrs. Trübner & Co.

A REPORT on excisions of the head of the femur for gunshot injury, by Mr. G. A. Otis, assistant-surgeon United States army, is the latest of a series of elaborate reports on important medical and surgical questions, published by the Surgeon-General of the War Department at Washington. The liberality of the Government of the United States in matters of science is, or at least should be, well known; and the handsome form in which these volumes, illustrated by numerous woodcuts, lithographs, and chromolithographs, are issued, deserves notice at our hands, although questions of practical surgery lie outside the province of NATURE as understood by us. In the volume we have, first, an apparently exhaustive historical survey of the operation of excision at the hip, and then the detailed records of the operation during the late civil war, these records being illustrated by figures of the pathological specimens and lithographs of individuals successfully operated on: finally, the records of temporisation are discussed, and the results compared with excision and amputation. Whether the surgical reader will endorse Mr. Otis' conclusions or not, they will, we are sure, agree that his report is in every way creditable to American military medical science.

PROFESSOR GRANT, the director of the Observatory in the University of Glasgow, has printed two letters, which he addressed to M. Leverrier, on the authenticity of the documents respecting Newton, communicated to the Academy of Sciences by M. Chasles. These letters, which are now more than two years old, have since the exposure of the Newton-Pascal forgeries, become specially interesting. They must be read in connection with M. Leverrier's more recently indited brochure.

THE sixty-eighth annual election of office-bearers of the Philosophical Society of Glasgow was arranged to take place last night (Wednesday). Professor Grant retires from the office of senior vice-president, and the Rev. H. W. Crosskey from that of librarian. The following members of council retire by rotation: Mr. Ramsay, of Kildalton, Professor W. J. Macquorn Rankine, Sir William Thomson, and Mr. William Ramsay.

A LETTER from Gross-Gerau in the *Cologne Gazette*, dated last Saturday, quoted in the *Pall Mall Gazette*, says that on the previous Wednesday a gentle rumbling was observed twenty-five times, but only one shock; on Thursday there were twenty-three rumblings, and a shock about midnight. On Friday there were six violent shocks resembling those of the 30th ult., and in the night, up to 7 a.m., there were nine more shocks, accompanied by frequent thunder. During the morning of Saturday there was again a calm, but in the afternoon two violent shocks were felt, the last of which occurred very suddenly at 4.32. It is a very remarkable fact that these shocks have entirely altered in character from the earlier ones, being announced by a single thunderclap similar to the noise of a cannon shot fired at a distance of some miles, but much stronger. Their direction, too, is vertical instead of horizontal as before. The total number of shocks felt at Gross Gerau during the last three weeks is between seven and eight hundred. Most of the clocks and watches in the place have stopped, and the houses have all been more or less damaged, even those which are built of stone. The earthquake has also destroyed sixty-one chimneys. What if the volcanic region of the Eifel should burst open with its old activities, and the beautiful Laacher See and Pulvermaar, and the Mosenberg among others should favour us with phenomena which formerly one has gone at least as far as Vesuvius to see!

THE Royal Society has just issued Part I. of their 159th volume, the bulk of which is in very fair ratio to the importance of its contents. We have first a paper on Solar Physics, by Messrs. De La Rue, Stewart and Loewy, containing a first instalment of the measurements made with a view of making the solar photographs taken at Kew the basis of a new determination of the sun's astronomical elements: the privately-printed papers, with which all astronomers are familiar, are acknowledged to have been preliminary. The great Melbourne telescope is exhaustively described by Dr. Robinson and Mr. Grubb, and the description is accompanied by admirable and numerous plates, so that all may gain a very ample notion of the grand instrument from which so much may be anticipated. Terrestrial Magnetism is the subject of two papers, one by the Astronomer Royal, the other by Mr. Chambers; while prolific Prof. Cayley has three mathematical memoirs—one on Skew Surfaces otherwise Scrolls, another on the Theory of Reciprocal Surfaces, and the last on Cubic Surfaces. The Formation and Early Growth of the Bones of the Human Face, by Mr. Callender; the Osteology of the Solitaire or Didine Bird of the Island of Rodriguez, illustrated by ten exquisite plates by Ford, by Messrs. A. and E. Newton; the Developments of the Semilunar Valves of the Aorta and Pulmonary Artery of the Heart of the Chick by Dr. Tonge, are the papers which appeal to biologists; and Mr. Gore's paper on Hydrofluoric Acid, and one by Mr. Lockyer on Spectroscopic Observations of the Sun, are the other memoirs included in the volume.

WE have to record the death of an astronomer of European reputation, Mr. W. F. Donkin, F.R.S., Savilian Professor of Astronomy at Oxford, and Honorary Fellow of University College.

ASTRONOMY

Correction of Atmospheric Chromatic Dispersion

THE Astronomer Royal, in his last communication to the Royal Astronomical Society on the Transits of Venus, adverted to the injurious effect on the observations, which might possibly arise from the chromatic dispersion produced by the atmosphere, and suggested that probably an efficient corrective might be found, in the application of a glass prism of small refracting angle in the eye-piece of the telescope. In a subsequent communication on the same subject, after stating the optical theory, Mr. Airy continues:—Suppose, then, that we have a series of flint prisms ground to the angles 2°, 4°, 6°, 8°, 12°, 16°. And suppose that we use a telescope with power 120 or with power 240. Then the following table, showing the zenith distance at which the atmospheric dispersion is corrected, is easily computed; the refraction being calculated by the formula just given, and the zenith-distance corresponding to the refraction being taken from a common table of refractions:—

	Telescopic power 120.		Telescopic Power 240.	
Angle of Flint Prism.	Atmospheric Refraction.	Zenith Distance.	Atmospheric Refraction.	Zenith Distance.
°	′	° ′	′	° ′
2	1·8	61 58	0·9	43 7
4	3·6	75 16	1·8	61 58
6	5·4	80 15	2·7	70 32
8	7·2	82 52	3·6	75 16
12	10·8	85 34	5·4	80 15
16	14·4	87 3	7·2	82 52

For view with the naked eye it would be necessary to use a prism (of appropriate small angle) with its edge downwards; but, for view with an inverting telescope, the edge of its appropriate prism must be upwards.

The object I proposed is completely attained. It is made possible, by this construction, to examine a celestial body with delicacy and accuracy, under circumstances which would, without this construction, have rendered nice observation impossible.

The series of angles of the prism which I have given appears to me well adapted to general wants. I propose to furnish each of the principal telescopes to be used for the transit of Venus with a complete series of such prisms, arranged perhaps on a long slider. Care must be taken to make the thickness of the slider-frame as small as possible, inasmuch as it must be accompanied with another slider carrying dark glasses. It will probably be found best to place both sliders between the two glasses of the eye-piece. This slightly disturbs the elements of the calculation above; but in practice the selection of the best prism will always be matter of trial, and the disturbance of calculations will be unimportant.

Before closing this subject I will advert to a remark made by one of the most acute telescope-observers who have ever been known in this Society, the late Rev. W. R. Dawes. He states that, in general, a telescope performs better with one particular point of the edge of its object-glass upwards than in any other position. The explanation of this singular remark will be found, I think, in the combination of the effect of error of centering of the two lenses of an achromatic object-glass, with the effect of atmospheric dispersion. The centre of one lens (using the word "centre" to denote that part in which the tangent-planes of the two surfaces are parallel) ought to be exactly above the centre of the other lens. But it is not easy to make this adjustment perfect; the centre of one lens is frequently above a part of the other lens where the two surfaces have a slight inclination; and the refraction thus created produces in the image of every star a spectrum which rotates as the telescope-tube is made to rotate. In one position of the tube the atmospheric dispersion is opposed to this, and may wholly or in a great measure correct it; in the opposite position the atmospheric dispersion is added to it, and increases its injurious effects.

The atmospheric dispersion between B and G is about $\frac{1}{60}$th of the atmospheric refraction. At zenith-distance 45° it is nearly 1″, at 63° it is nearly 2″, at 80° about 5″. These are the lengths of the visible spectrum.

The Cause of the Incandescence of Meteors

THE incandescence of meteors was at first ascribed to their friction against the air, until in 1854 M. Regnault showed that this was not probable. M. Govi, of Turin, now affirms that the high temperature is due to the heat disengaged by the compression exercised on the air in front of them. This accounts for the fact that the interior of a meteor sometimes shows no signs of excessive heating, and that the hydrogen is not expelled.—[Bul. Association Scientifique de France, t. vi. 305.]

AMONG the points of interest touched upon at the last meeting of the Royal Astronomical Society was the extension to the approaching transit of Venus of Professor Young's suggestion to observe times of contact in solar eclipses by means of the gradual reduction of the length of the lines of the chromosphere, as observed in a spectroscope.

BOTANY

Spontaneous Motion of Protoplasm

PROF. J. B. SCHNETZLER records in the *Archives des Sciences Physiques et Naturelles*, some observations on the spontaneous motion of the protoplasm in the cells of the leaves of the common water-weed, the *Anacharis alsinastrum*. The writer remarks that whether the cause of the motion is found, as some have maintained, in the successive contractions or vibrations of the exterior layer of the protoplasm, which transmit themselves to the interior layers; or whether the successive displacements of the molecules is produced by causes purely mechanical, as others have held, it still remains to be explained what produces these contractions or displacements. It is incontestable that they are found only in living protoplasm. Prof. Schnetzler believes that the principal cause which provokes the motion is the chemical action of oxygen, which passes through the wall of the cell, and of which a portion is probably transformed into ozone under the influence of light, as occurs also in the globules of blood. The most strongly refracted rays of light have a marked influence on these currents, which are also no doubt affected by the currents of electricity which form, under the influence of water, between the surface of the leaf and the contents of the cells. The energy of the motion depends principally on the temperature, showing the greatest vigour between 16° and 20° C. In the point of view of mechanical theory, we have here evidently an example of the transformation of light and of heat into motion. The *Anacharis* is especially favourable for the observation of these motions; as, in consequence of the transparency of its tissue, they can be watched under the microscope without any preparation.

THE Lucerne crops in several parts of the country have recently been attacked by a species of Dodder, the *Cuscuta hassiaca*, allied to the parasitic Clover-dodder and Flax-dodder, which are so destructive to those crops. It is described as being a beautiful plant, with clear orange leafless stems, and abundant pure white and exquisitely-scented flowers.

THE magnificent "Flora Crasiliensis," the *magnum opus* ot the late Von Martius, published under the auspices of the Bavarian and Brazilian Governments, is not likely to suffer by the death of that distinguished botanist. Under the able editorship of Dr. Eichler, of Münich, two new parts have recently been published, a most valuable and beautifully illustrated dissertation on the curious parasitic *Balanophoræ* by the Editor, and a monograph of the Brazilian *Convolvulaceæ* by the veteran Meissner. In the course of the ensuing winter we are promised a volume on the Ferns, about 350 species, with nature-printed illustrations, by Mr. J. G. Baker, of the Kew Herbarium; and the most eminent European botanists are engaged on other orders which still remain to complete the work. A. W. B.

CHEMISTRY

Italian Mineral Waters

THE following analyses of Italian Mineral Waters have been made by Prof. Purgotti of Perugia [Ann. di Chim. app. July, 1869, p. 59.]

I. Bromo-ioduretted water which collects in a reservoir, five kilometres from the station of Assisi :—

Carbon dioxide	0·44110
Silica	0·01500
Magnesium bromide	0·00124
Magnesium chloride	0·18830
Magnesium sulphydrate	0·07750
Sodium chloride	0·86370
Sodium sulphate	0·15630
Calcium bicarbonate	0·35800
Magnesium bicarbonate	0·25190
Extractive organic matters	0·02150
Total mineral constituents	2·37454
Water	907·62546
	1000·00000

This water likewise contained free oxygen, ozone, ferrous bicarbonate, and alumina (and iodine?), but in quantities too small for estimation.

II. A ferruginous water collected in a square reservoir about half a kilometre from Cannara, near Collemancio, was found to contain :—

Ferrous bicarbonate	0·0300 grm.	Magnesium bicarbonate
Manganous bicarbonate	0·0036	Magnesium chloride
Free carbon dioxide		Magnesium sulphate
Atmospheric air		Silica
Calcium bicarbonate		Calcium sulphate

The temperature of this water is considerably lower than that of the surrounding air.

Sal-ammoniacum Martiale

ANGELO BANIERI has made the following observations on the ammonio-ferric sulphate (*sal ammoniacum martiale*) collected on the lava of Vesuvius. Many naturalists believe that the hydrochloric acid evolved by lavas in their course, unites with the iron of the same lavas, forming ferric chloride, which, together with the ammonia of the air, gives rise to the compound of sal-ammoniac and ferric chloride found in the fumaroles. This view, however, does not appear to the author to be in harmony with facts observed in the Vesuvian lava-current of 1850. It was only in that part of the lava which had overwhelmed a cultivated and manured soil that fumaroles existed, and there they were so numerous as to yield more than 100 measured quintals of sal-ammoniac, whereas, on the other part of the igneous current, which had passed over an older lava of the year 1834, in which there was nothing but dry rock and sterile sand, there were no fumaroles of sal-ammoniac. The silica of the lavas acts at very high temperatures on the common salt contained in the manured soil, liberating hydrochloric acid, which, on the one hand, reacts on the ferric hydrate contained in the same soils, producing ferric chloride, and, on the other hand, decomposes the ammonium carbonate eliminated from the organic substances of the soil, which are subjected to dry distillation by the heat of the invading lava. The hydrochloric acid which gives rise to the sal-ammoniac of the fumaroles of volcanic lavas, cannot be derived from the lavas themselves, inasmuch as its presence is only transient; but it is derived from the decomposition of the chlorides contained in the invaded lands. An inspection of the lava of 1850 shows indeed that the denuded soil has been completely burnt, and nothing is seen but scoria of a reddish sand, which have evidently been subjected to a very high temperature.—[Ann. di. Chim. app. alla Med., July, 1869, p. 61.]

TIGRI has observed that the flowers of the hop have the power of destroying the vitality of the *Mycoderma vini.* A quantity of this fungus situated at the bottom of a vessel full of wine was found to be so completely disorganised by contact with the hop-flower, that it had no further effect in promoting the fermentation of the wine. Tigri accordingly recommends the use of hops for preserving wine.—(Ann. di Chim. app. alla Med., July, 1869, p. 20.)

M. VICTOR MEUNIER communicates to *Cosmos* the result of an experiment made in a Pasteur's flask. Seventy-five cubic centimeters of urine were introduced into a flask of three hundred cubic centimeters capacity, boiled for five minutes, and sealed. At the end of fifty-seven days two clusters of vegetation appeared; they proved to be a new species of Aspergillus, which the author, with some humour, dedicates to M. Pasteur. In another experiment, to the details of which we need not refer, M. Meunier discovered an additional species of Aspergillus, which he has named *gibbosus*.

PROFESSOR ROCHLEDER has found a new colouring ingredient in madder, in addition to alizarine and purpurine, its well-known constituents. The dye is soluble in both water and alcohol, crystallising from the latter in orange-yellow needles. The boiling aqueous solution, mixed with a little acetic acid, communicates a beautiful golden tint to wool or silk. Madder root contains, unfortunately, too small an amount of this substance to render its industrial extraction profitable.

OPINIONS seem still divided as to the poisonous nature of coralline and solferino red. Two cases are reported in *Cosmos*, from which we learn that wool impregnated with these colours produces loss of appetite, distaste for food, and cephalalgia. The wool became harmless after washing.

M. V. MARCHAND proposes to apply a chemical remedy to the newly-discovered disease of the vine. He thinks it certain that a saturated solution of sulphuretted hydrogen in water, or a mineral mixture which gradually evolves the gas, will effectually destroy the grubs which are now, in many vineyards, busily devouring the roots.

THE second part of the third volume of Dr. Kolbe's "Ausführliches Lehrbuch der Organischen Chemie" has appeared. This work, which will be complete in another volume, is a sequel to the well-known Graham-Otto's Chemie. The portion of it now before us treats principally of petroleum and similar oils, resins and balsams, albuminous bodies, biliary and cerebral products, and the constituents of urine.

GEOLOGY

Steneosaurus

MR. J. W. HULKE has published an elaborate description of the remains of a fossil crocodile from the Kimmeridge clay of Dorsetshire, which he identifies with Cuvier's *Deuxième Gavial d'Honfleur*, named *Steneosaurus rostro-minor* by Geoffroy Saint-Hilaire, and also as belonging to Quenstedt's genus *Dakosaurus*. The last-named genus will therefore be synonymous with *Steneosaurus* (Geoff. St.-Hil.).—[Quart. Journ. Geol. Soc., No. 100.]

On Sphærodus Gigas

IN a paper containing descriptions of two new species of *Gyrodus*, Sir Philip Egerton has described and figured the vomer of *Sphærodus gigas*, the discovery of which is interesting as proving the validity of the genus. In its character it is quite distinct from the same part in *Lepidotus*, to which genus the species has been referred on account of the resemblance of the detached teeth. The specimen figured contains a median row of six circular teeth, on each side of which is a row of seven rather smaller circular teeth. Sir Philip Egerton also describes and figures a beautiful specimen of the vomer of a *Gyrodus* from Kimmeridge, which he ascribes to one of his new species.—[Quart. Journ. Geol. Soc., No. 100.]

The Geology of Thrace

DR. A. BOUÉ, who has been investigating the geology of Thrace, announces some of the results of his expedition. He has traced the cretaceous and nummulitic formations from Jarim Brugas to Adrianople, and found crinoids in the shales and limestones near Eski Sara, one of which he is inclined to identify with the carboniferous limestone. The steep southern declivity of the Balkan represents a great fissure of dislocation, the granitic central stock of the ancient Balkan having sunk down bodily during the enormous porphyritic and trachytic eruptions; hot water flows from the fissures of the sunken granite, and forms numerous baths along the foot of the Balkan. In Mechli ravine, near Kisantik, immediately surrounded by mountains 4,000 feet in height, Dr. Boué discovered, resting directly upon gneiss, an old carboniferous formation, with three beds of good coal; but as no fossils were to be detected in the deposit, he was unable to determine whether it belongs to the coal measures. Coal-beds, probably of Eocene age, occur in the Rhodopi.—[Proc. Imp. Geol., Institute of Vienna, 31st Oct., 1869.]

PHYSICS

The Dynamics of Prince Rupert's Drops

PROFESSOR DUFOUR, of Lausanne, has been engaged in a research on the Development of Heat which accompanies the explosion of Prince Rupert's Drops. The examination of bodies which, in modern language, are said to be in a state of "molecular tension" is of the highest importance to dynamics, and the investigation to which we now refer is an example of the kind of work that is really required.

Every one is familiar with the pulverisation and explosion, so disproportionate to the mechanical force exerted to produce them, which are witnessed on the fracture of the point of one of these drops. M. Dufour finds, in addition, that an appreciable amount of heat is evolved at the same time. The simplest mode of exhibiting this effect is to adjust the drop in the cone of a vertical thermopile in such a manner as to prevent the powder produced by the disruption from projection elsewhere than against the upper face of the pile. This is easily accomplished by means of a caoutchouc cover, through which the point of the drop alone projects; and the entire apparatus, abundantly surrounded with cotton, is left at rest for a day. The pile is then connected with a galvanometer, and, after breaking the point, the required observation is readily made. With drops of 4·8 to 7·7 grammes, M. Dufour obtained a deflection of 5° to 9°. The mere friction of powdered glass gave no deflection. Attempts to determine the heat evolved were also made with the calorimeter, turpentine being the liquid employed. In their original form, these did not succeed; but tolerably concordant results were arrived at by effecting the explosion in a cone of pasteboard, having its base uppermost, and forcing the whole of the fragments to fall through the truncated vertex into the turpentine. In this way, it appeared that a weight of the drops, amounting to 11·40 to 20·42 grammes, caused an elevation of temperature of 0·25° to 0·35°. The internal condition of the glass was found, by these experiments, to vary appreciably in drops of different sizes. Sometimes the product consisted chiefly of large fragments, sometimes it was principally powder. M. Dufour compares the state of the drops to a rigid enclosure bound together by highly-heated bars, themselves mutually connected in every direction. After cooling, the bars would all be under strain, from which, if released at one part, the whole would be set free. Now, Joule and Edlund have shown that a strongly-stretched wire, if allowed to return to its original volume, actually evolves an amount of heat, forcibly reminding one of that developed in the present instances.

In order to discover the part of the drop whence the fragments had been derived, its exterior was coloured. Thus it was found that the largest fragments came from the central, the finest powder from the superficial layer; and the pieces that were examined had, as might thence be expected, the form of a very flat wedge. The evolution of heat during the explosion might have been presumed to be accompanied by an increase in the density of the glass; but although this is a point somewhat difficult to ascertain experimentally, M. Dufour's paper is not without evidence in favour of such being really the fact.

PHYSIOLOGY

Kinship of Ascidians and Vertebrates

The number of Max Schultze's *Archiv* (v. 4), just published, contains a letter to the editor from Prof. Kupffer, of Kiel, in which that distinguished embryologist asserts that he has been studying the early history of a species of Phallusia, and that his results in large measure agree with those of Kowalevsky touching the startling vertebrate features of the early condition of these invertebrata. He reserves for the present the details about the exact formation of the nervous system, but quite confirms the fact of the existence of a notochord. He says: "At this stage one could not imagine a more beautiful model of a vertebrate embryo, with the neural tube on one side of the axis and a visceral tube on the other." He, moreover, describes in his species of Phallusia the neural tube as not merely an almost spherical vesicle, but as prolonged in the form of a fine hollow thread into the tail above the notochord or axis. He promises full details shortly, and we hope to be able to return to this most important matter.—M.F.

The Chloral controversy seems likely to terminate. *Pure* chloral, M. Bouchut informs us, is really a good anæsthetic. On the other hand, M. Laborde says that its frequent administration is attended with danger. Chloral, if mixed with blood outside the body, yields no chloroform until traversed by a current of air.

SOCIETIES AND ACADEMIES

Ethnological Society, November 9.—This society held its first meeting for the present session at the rooms in St. Martin's Place. Professor Huxley, the President, occupied the chair. After some remarks by Colonel Lane Fox, the honorary secretary, on the Megalithic Monuments of Stonehenge, Mr. Gardner, of H.M. Consular Service, China, read a paper before the Society, on the Chinese People, Government, &c. The point on which Mr. Gardner laid most stress—in fact, the leading idea of the whole paper—seemed to be the tenacity with which the Chinese had preserved the usages of antiquity, and the skill with which they had adapted them to the exigencies of modern times. They retain, according to him, the patriarchal theory of government, but make it suitable for an empire of 400,000,000 human beings. And if we allow that the ideographic form of writing is the most ancient of all, then the Chinese, in this nineteenth century, preserve an older principle of expressing thought than is to be found in the most ancient Egyptian hieroglyphics extant, and yet no language in the world is more capable of finding appropriate terms for the latest discoveries in mental and physical science, and the newest inventions of art. Mr. Gardner pointed out some analogies which he fancied existed between Chinese, Egyptian, and Hebrew, leaving it to philologists to decide whether these supposed coincidences were fortuitous, or a confirmation of the theory set forward by Hunter and others, of the original unity of the Aryan and non-Aryan languages. In the Chinese religion, Mr. Gardner stated, that whatever might be the nominal creed of individuals, or even masses, ancestral worship (undoubtedly the most ancient form of religious cult) as an act of devotion is most universally practised in the present day. Underlying all religious forms and creeds, Mr. Gardner stated, was an idea, more or less vague, of one Supreme Being; but he did not express an opinion as to whether this idea is a legacy of ancient times, or one of modern development. Besides this leading idea, Mr. Gardner gave a long account of the Chinese social institutions and benevolent societies: these latter are somewhat remarkable, and though not general enough in their organisation to refute the prevailing idea that the enthusiasm of humanity is peculiar to Christianity, tend to show that the Chinese are more philanthropic than any other heathen nation. Mr. Gardner also read some notes, and gave some anecdotes of personal experience to elucidate his main theories. In conclusion, if Mr. Gardner is correct in his premises, we see no reason to doubt his conclusion, that when the theory of division of labour shall be put in practice with regard to races as well as individuals, the Chinese will play an important part in the world's history as ethical philosophers, merchants, mechanics, and labourers; but that they are unfitted for rulers, soldiers, or the higher walks of art, and will not tend to advance physical or mechanical science.

The President referred to the similarity between certain Chinese customs and those of the Polynesians; such as the exclusion of a word occurring in the name of a great chief. In like manner, the prohibition of marriage between persons of the same surname is a custom common to the Chinese and the Australians. In concluding the discussion, he alluded to the popular but erroneous notion that the Chinese were modified Mongols, and pointed to the fact that, although both had long black hair on the head, and only scanty hair on the face, yet the Chinese had a long skull, with prominent brow-ridges, whilst the Central Asiatic had a broad skull, deficient in brow-ridges.—Captain Sherard Osborn advocated the introduction of railways and the opening of mines; and pointed to the many other advantages which the Chinese would receive from their intercourse with Europeans.—The Rev. Prof. Summers, Dr. Hyde Clark, Dr. Leitner, and others, took part in the discussion.

Additional interest was given to the meeting by the presence of the Yarkandi brought to this country by Dr. Leitner, the only native of Yarkand who has ever visited Europe.

Geological Society, November 10.—Prof. T. H. Huxley, LL.D., F.R.S., President, in the chair. Mr. E. Hartley, of the Geological Survey of Canada, Montreal, was elected a Fellow of the Society. The following communications were read:—"Australian Mesozoic Geology and Palæontology," by Charles Moore, Esq., F.G.S. The author referred to the observations of Professor M'Coy and the Rev. W. B. Clark, on the occurrence of fossils of Mesozoic age in Australia, and then proceeded to notice the species which he had obtained from that region. Fossils of Mesozoic type occur both in Western Australia and Queensland, but the specimens have hitherto been found in apparently drifted blocks, and nothing is known of the bedded rocks from which they are derived. The author stated that the Australian Mesozoic fossils agree, not only in genera, but also in many cases in species with British forms; and he gave a list of species from Western Australia, identical with British species, from the Middle and Upper Lias, the Inferior Oolite, and the Cornbrash. Of the fossils from Queensland also, many are said to be identical with, or very nearly allied to, British species, but the author regards the general type of the Queensland remains as referring them to the Upper Oolite. A gigantic species of *Crioceras* is regarded by the author as possibly indicative of the occurrence of Neocomian deposits in Australia. The fossil evidence upon which Professor M'Coy inferred the occurrence of the Muschelkalk in Australia, was said by the author to be nugatory, his supposed *Myophoria* proving to be a *Trigonia* nearly allied to *T. gibbosa* of the Portland Oolite, and his doubtful *Orthoceras* a small *Serpula*. The author had found no indications of the existence of Triassic or Liassic deposits in Queensland. The blocks from Western Australia, referred by the author to the Middle Lias, contain *Myacites liassianus* (Quenst.), and are quite as highly ferruginous as the English Marlstone. The species identified by the author with British Oolitic species would indicate a range from the Inferior Oolite to the Cornbrash; the author suggests that the species may have had a longer range in time in Australia than in England, or that the subordinate divisions of the Oolite were not clearly marked in the Australian Mesozoic deposits. He is inclined to refer the fossils to the period of the Inferior Oolite. The author inferred from the occurrence of these Mesozoic fossils in drifted blocks, at the two extremities of Australia, separated by 38° of longitude, that an enormous denudation of rocks of the secondary series has taken place over a considerable part of Australia. Descriptions of a great number of new species were appended to the paper.

"On a Plant- and Insect-bed on the Rocky River, New South Wales," by Charles Moore, Esq., F.G.S. The organic remains noticed by the author were found by him in a small block of chocolate-coloured, micaceous, laminated marl, obtained from a bed about ten feet thick, at a depth of 100—110 feet, in the auriferous drifts of Sydney-flats, on the banks of the Rocky River. The author found the leaves of two forms of Dicotyledonous plants, fragments of a flat narrow leaf, which he refers to the Coniferæ, a seed-vessel, and the impressions of several seeds. The insect-remains consist principally of the elytra of beetles, among which Buprestidæ appear to predominate. The vegetable remains seem to indicate that the deposit is of Tertiary age.

Prof. T. Rupert Jones mentioned the discovery of a large *Crioceras* in the Jurassic beds near Port Elizabeth.—Mr. W. Boyd Dawkins suggested that we had hardly a right to apply the European standard in judging fossils from all parts of the world, and doubted whether, if these fossils were examined from the purely Australian point of view, the same age would be assigned to them.—Mr. Seeley agreed with Mr. Dawkins, and argued from the existence of natural groups in different areas of the globe, that the same must have been the case in former ages.—Mr. R. Tate remarked that if Mr. Moore had compared the Jurassic fauna with those of India, Africa, and Chili, he would have found the same mixture of forms belonging apparently to different horizons. He considered that the Australian fossils probably represented our Middle Oolite. He did not quite agree with the author as to some of the specific determinations.—Dr. Duncan remarked that the same combination of forms separated in Europe was found in the Tertiary fossils of Australia. He thought that further facts were necessary before forming a decided opinion as to the succession of beds in that continent.—The President remarked that when we talked of identity of fauna in Australia and this country, improbable as it might appear, we must remember that at the present time identical species, and, to a great extent, a similar fauna, were to be found in our seas more than 180° apart.—Mr. Moore, in reply, argued that it was the safest plan to follow the well-established standard of Europe even in remote parts of the world. He was inclined to refer the bulk of the specimens rather to the Lower than to the Middle Oolite, but otherwise he agreed in the main with Mr. Tate.

"On *Hypsilophodon*, a new Genus of *Dinosauria*," by Prof. Huxley, F.R.S., President. The author described the characters presented by the skull of a small Dinosaurian reptile obtained by the Rev. W. Fox from a Wealden bed at Cowleaze Chine in the Isle of Wight. One of the most striking peculiarities of this skull was presented by the præmaxillary bone, which seems to have been produced downwards and forwards into a short edentulous beak-like process, the outer surface of which is rugose and pitted. The author remarked upon the known form of the symphysial portion of the lower jaw in the Dinosauria, and indicated that its peculiar emargination was probably destined to receive this beak-like process of the præmaxillaries, which may have been covered either by fleshy lips or by a horny beak. The dentigerous portion of the præmaxilla bears five small conical teeth. The alveolar margin of the maxilla bears ten teeth, which are imbedded by single fangs, and apparently lodged in distinct alveoli. The summit of the crown, when unworn, is sharp, and presents no trace of the serrations characteristic of *Iguanodon*, but it is sinuated by the terminations of the strong ridges of enamel which traverse the outer surface of the crown. The teeth thus present some resemblance to those of *Iguanodon;* but the author regarded the two forms as perfectly distinct, and named the species under consideration *Hypsilophodon Foxii*. Of the lower jaw the right ramus is present, but its distal extremity is broken off, and its teeth are concealed. On the outer surface of the lower jaw the centrum of a vertebra is preserved. The author then referred to a fossil skeleton in the British Museum, which has been regarded as that of a young *Iguanodon*. It is from the same bed as the skull previously described. The author remarked that, in form and proportions, the vertebræ were quite different from those of *Iguanodon*, and apparently identical with those of his new genus, as shown by the centrum preserved with the skull; the animal had at least four well-developed toes; and other peculiarities were indicated, which seem to prove that it was quite distinct from *Iguanodon*. This skeleton the author identified with his *Hypsilophodon Foxii*, and described its characters in detail, dwelling especially upon the peculiarities of the pelvic bones, which are singularly avian in their structure.

"Further Evidence of the Affinity between the Dinosaurian Reptiles and Birds," by Professor Huxley, F.R.S., President. In this paper the author reviewed the evidence already cited by himself and others (especially Prof. E. D. Cope), in favour of the ornithic affinities presented by the Dinosauria; and discusses at length the recently ascertained facts which bear upon this question, some of the most important of which are derived from the species described by him in the preceding paper under the name of *Hypsilophodon Foxii*. He summed up his paper by a comparison of the different elements of the pelvic arch and hinder limb in the ordinary reptiles, the Dinosauria and Birds, and maintained that the structure of the pelvic bones (especially the form and arrangement of the ischium and pubis), the relation between the distal ends of the tibia and the astragalus (which is perfectly ornithic), and the strong cnemial crest of the tibia and the direction of its twist, furnish additional and important evidence of the affinities between the Dinosauria and Birds.

Sir Roderick Murchison, who had taken the chair, inquired as to the habits of the *Hypsilophodon*.—Mr. Hulke mentioned that Mr. Fox had several blocks containing remains of a large portion of the *Hypsilophodon*, all procured from a thin band of sandstone near Cowleaze Chine. On one the pelvis is almost entire, as well as the right femur, the tibia, which is longer than the femur, four long metatarsal bones, and an astragalus. All the long bones are hollow. Portions of at least eight individuals have been found in the same bed.—Mr. Seeley doubted whether these animals should be called Reptiles at all, as they seemed to him to form a group distinct alike from reptiles, birds, and mammals, but occupying an intermediate position. In the hinder limbs of *Pterodactylus* the analogies were closer with mammals than with birds. He thought it possible that the peculiar structure of the hinder limbs of the Dinosauria was due to the functions they performed rather than to any actual affinity with birds.—The President, in reply, stated that *Hypsilophodon*, from the character of its teeth, probably subsisted on hard vegetable food. He expressed a hope that Mr. Fox would allow a closer examination of his specimens to be made. He was unable to agree with Mr. Seeley's views. He was inclined to think that the progress of knowledge tended rather to break down the lines of demarcation between groups supposed to be distinct than to authorise the creation of fresh divisions.

Specimens illustrative of their respective papers were exhibited by C. Moore, Esq., and Prof. Huxley.

Institution of Civil Engineers, November 9.—At the first ordinary general meeting of the session, held on Tuesday, the 9th inst., Mr. Charles Hutton Gregory, the President, made some observations on the action taken by the council with reference to a notification gazetted by the Public Works Department of the Government of India. In this notification it was alleged that the Governor-General in Council was given to understand, that in the civil engineering profession in England it was a recognised practice for civil engineers employed by public companies and otherwise, to receive, in addition to the salaries paid them by their employers, commission on contracts given out, or stores and materials ordered or inspected by them, and other like pecuniary considerations for services done, or intended to be done, which were considered legitimate sources of emolument. The Council had met, and unanimously passed a series of resolutions, emphatically denying that such practices were recognised in the profession, and asserting that any engineer detected in such practices would be held to be guilty of disgraceful conduct, which would disqualify him from being a member of this Institution. Regret was expressed that so grave a charge should have been received and published by the Government of India without proper inquiry, as such inquiry would have shown that the charge was absolutely untrue; and, having reference to the grievous wrong which such an imputation, stamped with such authority was calculated to do to an honourable profession, an appeal was made to the Government of India to cause the scandalous statement to be withdrawn. This protest was transmitted to the Secretary of State for India, who had received a deputation from this Institution, comprising the President and every member of Council then in London. The Duke of Argyll promised to investigate the case, and has put on record that "he regards with implicit confidence the indignant repudiation by the Institution of any recognition of the practice referred to in the notification."

Mathematical Society, November 11.—The first meeting of the present session was held on Thursday, the 11th inst., Prof. Cayley, F.R.S., President, in the chair, when the following gentlemen were elected to be the council for the session 1869-70:—President: Prof. Cayley, F.R.S. Vice-Presidents: A. De Morgan, F.R.A.S., W. Spottiswoode, F.R.S., Prof. Sylvester, F.R.S. Treasurer: Prof. Hirst, F.R.S. Hon. Secretaries: M. Jenkins, M.A., R. Tucker, M.A. Other members: W. K. Clifford, B.A., T. Cotterill, M.A., M. W. Crofton, F.R.S., Olaus M. F. E. Henrici, Ph.D., S. Roberts, M.A., J. Stirling, M.A., A. Smith, F.R.S. L. and E., Prof. H. J. S. Smith, F.R.S., and J. J. Walker, M.A.

The Rev. James White, M.A., was elected a member. Mr. Tucker read a communication from Mr. G. O. Hanlon, on the "Vena Contracta," and Mr. Jenkins a letter from Mr. Clerk-Maxwell, containing the question, "Can the potential of a uniform circular disk at any point be expressed by means of elliptic integrals? Suppose V is the potential of the disk bounded by the circle $z=0$, $x^2+y^2=a^2$.

Then $$\frac{dV}{dx} = 2x \sqrt{\frac{a}{r}}\ \frac{1}{\sqrt{c}}\ (E-F)$$

where $$r^2 = x^2 + y^2;$$

and if AB be a diameter parallel to r,

$$c = \frac{PB - PA}{PB + PA}$$

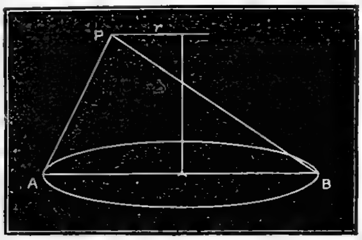
and E, F are complete elliptic functions for modulus c;

also $$\frac{dV}{dy} = 2y \sqrt{\frac{a}{r}} \cdot \frac{1}{\sqrt{c}} (E - F)$$

$$\text{But } \frac{dV}{dz} = w,$$

where w is the solid angle subtended at P by the circle, that is the area of the spherical ellipse on a sphere of unit radius cut off by the cone whose vertex is P, and base the circle.

We have expressions for $\frac{dV}{dx}$ and $\frac{dV}{dy}$, can $\frac{dV}{dz}$ also be expressed by elliptic functions, and if so, can V itself be so expressed? I am writing out the theory of electric currents in which these quantities occur. The expression for $\frac{dV}{dz}$ for an elliptic disk can be found if we know it for a circular one; for the spherical ellipses in the one case are no more complicated than in the other. Can $\frac{dV}{dx}$, or V itself, be found for the elliptic disk?"



The President and Mr. C. W. Merrifield spoke on the question, but could not decide for or against it impromptu.

Mr. T. Cotterill then gave an account of his paper on Opposite Points on a Curve. The subject bore reference to two former papers read before the society by the author and by Prof. Sylvester, the Theory of Residuals, not yet, to the regret of the society, put into a shape for publication. Mr. S. Roberts and Mr. W. K. Clifford took part in a discussion upon this paper.

Royal Microscopical Society, November 10.—Rev. J. B. Reade, M.A., F.R.S., President, in the chair. A communication from Dr. Pigott on high power definition with illustrative examples was read. The paper had special reference to the markings on the Podura scale, of which the writer claimed to have discovered the true nature. As the result of close and protracted observation, Dr. Pigott believes that he has resolved these markings into rows of bead-like bodies essentially differing in their character from the "note of exclamation" markings so familiar to microscopists.—Another paper on a cognate subject, entitled the Scales of certain Insects of the order Thysanura, was read by Mr. S. McIntyre. Mr. McIntyre's examinations of the genus of the family of the *poduridæ* leads him to express conclusions confirmatory of the views hitherto entertained, as to the nature of the markings seen under the microscope; and in the discussion which followed the opinions expressed by the Fellows were entirely in support of Mr. McIntyre's conclusions. Among the donations announced was an interesting specimen of an Amici reflecting microscope, working on the principle of the Newtonian telescope.

Zoological Society, November 11.—Mr. George Busk, F.R.S., V.P., in the chair.—The Secretary made some remarks on the more remarkable additions to the Society's Menagerie during the past summer, amongst which particular attention was called to some Amherst's pheasants, deposited by J. J. Stone, Esq.; an Owen's apteryx, presented by the Acclimatisation Society of Otago, New Zealand; a pair of the newly-discovered Chinese deer (*Elaphurus davidianus*), presented by Sir Rutherford Alcock; and a young male Spanish ibex, presented by Major Howard Irby.—Extracts were read from a letter addressed to Mr. Grote by Dr. John Anderson, C.M.Z.S., containing observations respecting the pigmy hog of the Terai (*Porcula salvania*), and other animals which he is endeavouring to procure for the Society's Menagerie.—A letter was read from Dr. G. Bennett, containing an account of the habits of the wood-hen of Lord Howe's Island, as recently observed by Mr. R. W. Fitzgerald.—Mr. Sclater exhibited a specimen of the so-called wood-hen, which had been forwarded in spirits by Dr. Bennett to the Museum of the Royal College of Surgeons, and stated that it was a rail of the genus *Ocydromus*, apparently hitherto undescribed, which he proposed to call *Ocydromus sylvestris*.—A letter was read from Mr. Morton Allport, F.Z.S., containing an account of the successful introduction of the salmon trout (*Salmo trutta*) into Tasmania.—Mr. Quelch exhibited a remarkable specimen of a fish of the genus *Rhombus*, supposed to be a hybrid between the turbot and the brill.—Mr. J. W. Clark, F.Z.S., exhibited some mounted skeletons of the extinct dodo of the Mauritius, and of the male and female solitaire of the Island of Rodriguez, belonging to the Cambridge University Museum.—Mr. E. Ward exhibited a curious melanoid variety of the woodcock (*Scolopax rusticula*).—Professor Flower, F.R.S., read a memoir on the anatomy of the Aard-wolf (*Proteles cristatus*), founded on a specimen recently deceased in the Society's Menagerie. The result arrived at after a careful examination of every part of this animal was that *Proteles* constituted of itself a distinct family of carnivorous animals, allied to the *Hyænidæ* and *Viverridæ*, but more closely to the former than Mr. Flower had previously supposed when he had only the skull of this remarkable animal to judge by. Mr. Flower's paper was illustrated by the exhibition of the stuffed skin, a complete skeleton, and a full series of anatomical preparations of the internal organs of this animal, all taken from the same individual.—A communication was read from Dr. J. G. Gray on the guemul or roebuck, from Tinta in Southern Peru, which Dr. Gray considered to constitute a new genus of deer, proposed to be called *Xenolophus*.—A second communication from Dr. Gray contained a description of *Emys laniaria*, a new species of fresh-water tortoise, from an unknown locality.—A report was read by Dr. A. Günther on two collections of Indian reptiles, recently received by the British Museum, one of which had been formed by Dr. Leith in various parts of Western India; the second by Mr. Barnes in Ceylon. Both were of much interest, and contained various new species, which were characterised in the present paper.—A communication was read from Dr. B. Simpson, containing notes on the habits of *Ailurus fulgens*, as observed by him during his residence in Nepal.—A communication was read from Surgeon Francis Day, F.Z.S., containing the first part of a series of notes on the specimens of fishes in the Calcutta Museum. Mr. R. B. Sharpe read some additional notes on the genus *Ceyx*, in continuation of a former communication on this subject. The principal object of the present paper was to discuss the question of the identification of the true *Ceyx rufidorsa*, Strickland.

Brighton

Brighton and Sussex Natural History Society, November 8.—Mr. T. H. Hennah, President, in the chair. A rare grass, *Gastidium Lendigerum*, obtained in October, in the Weald of Sussex, by Mr. Davies, was presented by that gentleman.—A paper on Mosses was read by Mr. Smith, in which the development, growth, mode of reproduction, and the several parts of mosses were described and illustrated by enlarged drawings and microscopic preparations, while it was pointed out that to the microscopist they opened out fields of research and questions to be settled, unsurpassed by any other branch of natural history. Prior to reading the paper, Mr. Smith handed in a complete Bryological Flora of the county of Sussex, comprising 298 species and sub-species, a brief account of the soils in which the rarer species grow, together with an enumeration of those which, at present as regards Britain, have been found only in Sussex. This list will be published in the next annual report.

Brussels

Royal Academy of Sciences, October 9.—M. Schwann reported on the memoir by MM. Masius and Vaulair on the anatomical and functional regeneration of the spinal cord, of which a notice was given in the last number of NATURE. Besides the immediate subject of their memoir, the authors treat of the histology of the *filum terminale* of the spinal cord in the frog, and of the cutaneous and medullary distribution of the spinal nerves.—M. A. Quetelet communicated notes on the meteors observed at Brussels in August, 1869, and on that of the 1st October, 1869; and M. Terby noticed the meteors observed at

Louvain in August last.—Storm observations, from the 1st of June to the end of September, were presented; for Brussels by M. Quetelet, for Louvain by M. Terby, for Malines by M. Bernaerts, for Antwerp by M. C. Coomans, and for Gerpinnes, near Charleroi, by M. V. van Geel. M. J. Cavalier also communicated a note of storms observed at Ostend in August and September last.—M. Zantedeschi communicated a note on the employment of the outer armature of the submarine cable, while the inner armature, or isolated conducting wire, transmits the telegraphic despatch. The author remarks that the submarine cable represents a Leyden jar, and hence that when the conducting wire conveys a message, say from Europe to America, the same message is reconveyed to the European station by means of the wires forming the outer portion of the cable. He proposes to establish an apparatus at each station for the purpose of receiving this return message, so as to enable the operator to see that his message is correctly transmitted.—M. L. de Koninck stated, that on the 2nd October last, the day of the earthquakes in the Rhenish provinces, he experienced a slight double shock in Liège at about 11.40 p.m.

MANCHESTER

Literary and Philosophical Society. *Microscopical and Natural History Section*, Oct. 11.—Mr. John Watson in the chair. The President delivered an address, from which the following are extracts:—"It will interest all naturalists, and especially entomologists and lepidopterists, to hear that there has very lately been received in this country a fine specimen of the magnificent butterfly Papilio Antimachus, of which only one specimen was ever before brought to Europe. . . . . The Darwinian theory appears to be making progress among a certain class of naturalists, but its upholders display a disposition to avoid precision of terms, and to enlarge and confuse the meaning of the words they employ, rather than scientifically to limit and define them; they use variability and mutability as having one and the same meaning, instead of distinguishing one as referring to subdivision into varieties, and the other as change of specific forms. Just now, as a development of the theory of natural selection, we hear a great deal from some distinguished entomologists about imitation and mimicry, where resemblance would be the more correct word; and these terms cannot be said to be used figuratively, because it is argued that some species and genera of butterflies mimic the colourings and markings of others for the sake of protection from enemies, and for other aims and ends. Certainly the words imitation and mimicry imply foregone intention. Now it is probable that no butterfly ever saw its parent or ancestor, its offspring or posterity, and it is an absurd stretch of imagination that its own observation could induce and enable it to change the colouring and appearance of its successors; and if it had such ability and reasoning power, it would effect the change for protection from enemies in the larva, and not in the imago. We know that Nature loves to repeat her works, and it is common to find resemblances and repetitions through various and distantly allied families of animals, and they are truly connecting links in the chain of creation. The controversy is still going on between those who affirm and deny the existence of a vital principle of energy or force, and Professor Huxley stands foremost among the latter; very interesting microscopic observations have been made, and ingenious arguments have been deduced from them; but the grand step from the lifeless to the living protoplasm has not been diminished. Physiologists may, perhaps, hereafter discover and explain the difference between organic forms, living and dead; but at present it is not proved that the phenomena of life can be reconciled with the mere functions of matter."

Dr. Henry Simpson exhibited specimens of *Statice spathulata*, gathered by himself this autumn on Hilbree Island, Cheshire.

Mr. Tait sent a portion of the beach from near Alexandria, Egypt, consisting almost entirely of shells. He stated that for many miles along the coast the shore was of a similar character.

Mr. Joseph Sidebotham read a paper on varieties in Lepidoptera, from which the following passage is extracted:—"The questions as to what constitutes a species? where does a species end, and variety begin? and whether a species be a natural or merely an artificial division? are amongst the most difficult of solution in the whole range of natural history, and just at this time are very prominently before the scientific world. With a view to determine the influence which difference of food and light might have in modifying species, the author gives the following as the result of some experiments which he had made. I procured about 2,500 larvæ of the tiger moth, in a young state. I divided them into six lots, keeping each in a separate cage, and feeding them differently. One lot was fed on willow, another on butter burr (*Petasites vulgaris*), another on hawthorn, another on plum, one on dock, and one on nettle, grass, bramble, and various other kinds of food. A considerable proportion of each became perfect insects, and I could detect no difference whatever in the colours, from the food they had lived upon. That is to say, the variations in colour and marking were not to be traced in any case to the food. I kept several batches of eggs, and reared the larvæ carefully through the winter, and then again divided them, giving each lot a different kind of food. Again the same result. I found that one year the larvæ I had brought from the coast had usually the inferior wings more or less of a yellow shade, instead of the bright scarlet of the Cheshire specimens. Having for many years continued these experiments without obtaining any marked results, I this year tried another of a different nature. I selected the tortoiseshell butterfly, as one of the least variable species we have, and I procured several broods of young larvæ just emerged from the egg. These I kept in a dark box until I had all ready, and then I divided each brood into three lots, putting one-third into a box in my photographic room, which is lighted with orange-coloured glass, one-third into a box lighted with blue glass, and the ventilators carefully shaded so that only light of a blue colour could reach the larvæ, the remainder were put into an ordinary cage, in the natural light. The latter fed up and came out into butterflies in the usual time. Those in the blue light were not healthy, and though every care was taken, at least fifty or sixty died before changing, and a considerable number changed into chrysalides, and then died; those that came out into perfect insects were very much smaller than usual. Those lighted by orange-coloured glass fed up very well, but many of the two first lots had come out before one of them changed into chrysalis; scarcely one of them died, and I examined each one before I allowed it to fly, to see what effect had been produced. I retained a few specimens of each lot to exhibit this evening, and now proceed to describe the difference. Those reared in the blue light differ from the ordinary form in being on an average much smaller; the orange brown is lighter in shade, and the yellow and orange run into each other, instead of being distinct and separate. Those reared in the non-actinic, or yellow light, are also smaller, the orange brown is replaced by a salmon colour, the venation more strongly marked, and the blue dashes at the edge of the wings in the usual form, are in these of a dull slatey colour. A series of specimens of these side by side with those reared in ordinary light, are here for exhibition. One evening I found about 60 butterflies out of chrysalis, of those in the photographic room, and taking each one carefully I examined them all and allowed them to fly; shortly afterwards I found the whole of them had settled against the wall of the house, and presented a most remarkable appearance; they remained there more than half-an-hour, the western sun was shining against the wall, and it is not unlikely when, being suddenly brought from the red light, where they had spent all their lives, to the bright daylight, they have been so dazzled as to act in this peculiar manner. The results of this experiment do not show any very startling change in colour, such as one would have expected from the known effects of light on plants and from the occasional occurrence of very much more strange varieties, one now and then meets with, which cannot have been subject to such severe treatment; still, when we consider that even this difference is caused in one generation, and in the course of a month, it is a very suggestive fact, and leads one to think that light has certainly as much or more effect on the colours of Lepidoptera, than the difference of food, and might in a long series of generations lead to very material changes in both form and colour, and perhaps considerably modify our ideas of what constitutes a species."

MONTREAL

Natural History Society, October 25.—An important paper on the Gaspé fossils was read by Principal Dawson. The Peninsula of Gaspé, between the river St. Lawrence and the Bay des Chaleurs, was the first part of Canada explored by the Geological Survey under Sir William Logan, and it contains rocks representing four great geological periods, the Lower Silurian, the Upper Silurian, the Devonian, and the Lower Carboniferous; all admirably exposed in coast cliffs; and in the case of the Upper Silurian and Devonian abounding in characteristic fossils. The visit of Principal Dawson in the past summer had reference to further study of the interesting fossil plants of the Devonian sandstone, many species of which have been described in his papers in the *Canadian Naturalist*, and in the Journal of the Geological Society. With Messrs. G. T. Kennedy and G. W. Dawson as assistants, he explored the whole of the north side and the greater part of the south side of Gaspé Bay, and has obtained very large and interesting collections of fossil plants. Among these are two large trunks of *Protaxites Logani*, a new and beautiful species of *Psilophyton*, and a species of *Cyclostigma*, a genus hitherto found only in the Devonian rocks of Ireland. Several interesting animal remains were also found, including numerous species of large fishes (Mechæracanthus); and Mr. Kennedy was so fortunate as to find a *Cephalaspis*, the first representative of the genus as yet found in America. The animal fossils have been placed in the hands of Mr. Billings and Dr. Newberry for comparison, and the plant will probably be described in detail in the course of the coming winter. Specimens of some of the more interesting fossils above referred to, were exhibited to the society.—Mr. Ritchie read a paper on the small cabbage-butterfly (*Pieris rapæ*), the caterpillars of which have recently been extremely destructive in Canadian gardens. This insect is not indigenous to America, and was first noticed in Canada some years ago by Mr. W. Couper. Mr. Whiteaves made an interesting verbal communication on dredging in Gaspé, and exhibited a large series of marine invertebrates.

PARIS

Academy of Sciences, November 8.—M. Pasteur presented a note in reply to that of M. Thenard on the preservation of wines by heat. A memoir was read by M. H. Marès on the transformations undergone by powder of sulphur (flour of sulphur and powdered sulphur) when it is spread upon the soil, in which the author states that the sulphur which has been abundantly employed in the vineyards of France of late years becomes converted into sulphuric acid which combines with the lime of the soil to form sulphate of lime. The author has not ascertained whether the sulphuric acid is produced by direct oxidation of the sulphur, or by that of sulphuretted hydrogen formed by it in contact with manure, but he states that no odour of sulphuretted hydrogen is perceptible where the sulphur is used. The employment of sulphur appears to be effectual in preserving the vines from disease.—A note by M. J. Personne on the transformation of hydrate of chloral into chloroform in the animal economy was read. The author remarked that whilst M. Liebruch maintains that hydrate of chloral is converted into chloroform by contact with the alkali of the blood, the French observers have generally held an opposite opinion. In his experiments he found that where hydrate of chloral is added to blood, or administered to a dog, no production of chloroform is perceptible, but he obtained chloroform by the distillation of the blood. To avoid the objection that the heat employed in distillation might produce the conversion, he operated at a temperature of 40°—45° C. = 194°—113° F., conveying the vapour by a current of air through a red-hot porcelain tube into a solution of nitrate of silver. The reaction produced demonstrated the presence of chloroform in the vapour, no reaction being caused by vapour of hydrate of chloral conveyed and decomposed in the same way. Unlike M. Bouchet, the author detected no chloroform in the urine of animals to which hydrate of chloral had been administered.—M. J. V. Labordi communicated a note on the ill effects attending the administration of chloral.—In a note on chloride of gold, M. H. Debray remarked that although sesquichloride of gold is decomposed by exposure to a temperature of about 200° C. = 392° F., into proto- and per-chloride, it may, nevertheless, be volatilised by a heat of 303° C. = 572° F., in an atmosphere of chlorine. It then crystallises in long reddish needles.—M. A. Riche communicated a note on the bronze of sonorous instruments, relating chiefly to the production of gongs and cymbals similar to those made in China. Chinese metal contains about twenty per cent. of tin. Alloys made with these proportions of metal are very brittle when cold, but the author found that at a dull red heat they may be forged with ease, and produces very sonorous plates.—M. A. Landrin announced that yellow coralline is not poisonous, so that it may be employed for industrial purposes.—M. Petrequin presented a note on the chemical composition and comparative physiology of the cerumen of the mammalia. Its base is potash in man and the ox, lime in the dog, and magnesia in the horse.—M. A. Petit stated that in the melon the rind contains only glucose, as also the flesh whilst still green. During ripening cane-sugar is gradually developed in the latter, its formation commencing in the most acid part of the pulp surrounding the seeds.

DIARY

THURSDAY, NOVEMBER 18.

ROYAL SOCIETY, at 8.30.—Preliminary Report of the Scientific Exploration of the Deep Sea in H.M. surveying vessel *Porcupine*, during the summer of 1869, conducted by Dr. Carpenter, V.P.R.S., Mr. J. Gwyn Jeffreys, F.R.S., and Prof. Wyville Thomson, LL.D., F.R.S. And other papers.
SOCIETY OF ANTIQUARIES, at 8.30—Ancient British Barrows (Round): Dr. Thurnam.
LINNEAN SOCIETY, at 8.—Review of the genus *Hydrolea*, with descriptions of three new species: Mr. A. W. Bennett, F.L.S.
NUMISMATIC SOCIETY, at 7.
LONDON INSTITUTION, at 7.30.—Architecture, or the Fine Art of Building: Prof. Robert Kerr.
CHEMICAL SOCIETY, at 8.—On Namaqualite and Chemical Researches on new and rare Cornish Minerals—No. 6. A new Ferric Silicate: Prof. Church. On Chloranil and Bromanil—No. 2: Dr. Stenhouse.

FRIDAY, NOVEMBER 19.

PHILOLOGICAL SOCIETY, at 8.30.

MONDAY, NOVEMBER 22.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.
LONDON INSTITUTION, at 4.—Elementary Physics: Prof. Guthrie.

TUESDAY, NOVEMBER 23.

ETHNOLOGICAL SOCIETY, at 8.—On some Quartzite Implements of Palæolithic Type from the Drift of the Cape of Good Hope: Sir George Grey, Bart. On the Races and Languages of Dardistan hitherto undescribed: Dr. Leitner.

WEDNESDAY, NOVEMBER 24.

GEOLOGICAL SOCIETY, at 8.—On the Dinosauria of the Trias, with observations on the Classification of the Dinosauria: Prof. Huxley, F.R.S., President. The Physical Geography of Western Europe during the Mesozoic and Cainozoic periods, elucidated by their Coral-faunas: Dr. P. Martin Duncan, F.R.S., Sec.G.S.

THURSDAY, NOVEMBER 25.

ROYAL SOCIETY, 8.30.
LONDON INSTITUTION, at 7.30.—Architecture: Prof. R. Kerr.
LONDON MATHEMATICAL SOCIETY, at 8.
ZOOLOGICAL SOCIETY, at 8.30—Notes on some Spiders and Scorpions from St. Helena, with descriptions of new Species: Rev. O. P. Cambridge. On a small collection of Birds from the Tonga Islands: Dr. O. Finsch and Dr. G. Hartlaub.

BOOKS RECEIVED

ENGLISH.—Transactions of the International Congress of Prehistoric Archæology (Longmans).—The Universe; or the Infinitely Great and the Infinitely Little: F. A. Pouchet (Blackie and Sons).—Physical Atlas (A. K. Johnston).—Darwinism tested by the Science of Language: Professor A. Schleicher, translated by Dr. A. V. W. Bikkers (Hotten).—The Midnight Sky: Donkin (Religious Tract Society). Æsop's Fables, Illustrated by Ernest Griset (Cassell).

FOREIGN.—Die Befruchtung bei den Coniferen: Dr. E. Strasburger.—Die Maschinenfabrication: H. V. Reiche.—Berichte über die Versammlung der Deutschen Ornithologen-Gesellschaft. (Through Williams and Norgate.)

CONTENTS

Printed by R. CLAY, SONS, & TAYLOR, at 7 and 8, Bread Street Hill, in the City of London, and published by MACMILLAN & Co., 63, Bleecker Street, New York.—THURSDAY, November 18, 1869.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

Registered for Transmission Abroad.]

THURSDAY, NOVEMBER 25, 1869

A SCIENTIFIC CENSUS

CAN we reduce to the certainty of numbers the amount of interest taken in England in the advance of science? How many are there devoted to its pursuit? How many sufficiently concerned in its progress, as to be willing to make some sacrifices for its promotion? Interested in the results of science, ready to grasp its countless benefits, eager to catch its earliest gifts, we all are; but how many love science for its own sake, and are actively engaged in cultivating and promoting it? Are there not very many in this sordid age ready to exclaim with D'Ailly—

> Dieu me guarde d'être savant,
> D'une science si profonde
> Les plus doctes, le plus souvent,
> Sont les plus sottes gens du monde!

The Census of 1861 gave the number of persons engaged in the learned professions, or in literature, art, and science; and classed as "scientific persons," officers of literary and scientific societies, curators of museums, analytical chemists, and a certain number who styled themselves naturalists, botanists, geologists, mineralogists, chronologists, and civil engineers. These, however, with a number of professors and teachers, pursue science as a vocation. We prefer drawing our materials from the membership of our learned societies. Many of their members are, it is true, professors and teachers, yet they appear in a more congenial character as members of our academies, or fellows of our learned societies; and though it can scarcely be said that their members are in all cases absolutely men of science, or that all the men of science in the country are to be found in their lists, in them we have, at least, a goodly band of men associated together for the advance of science. Judging from the facilities such societies afford for the association of persons of kindred mind and taste, the common use of technical libraries and instruments, and the publication of their transactions, we are safe in assuming that they attract, at least, the greater number of men anxious to labour for the promotion of science.

First and foremost among our learned societies is the Royal. The Institute of France and other foreign academies are, in a manner, the creatures of the State; and their members are mostly all salaried. The Royal Society was, from the first, a voluntary society, and never derived any support from the State, though it administers from year to year a certain amount given by the State for the promotion of science. In 1831 the Royal Society had 791 members, but by a change introduced in 1847 the membership has undergone considerable diminution; and in 1868 the number was reduced to 600, the number admitted every year being considerably less than the number dying or retiring. It is the vocation of the Royal Society to admit within its circle the most distinguished men in all the branches of science, and we might even hope that, like the Institute of France, its membership may be divided into five Academies, such as the "Académie Française" for literature, the "Académie des Inscriptions et Belles-lettres" for history, the "Académie des Sciences" for sciences and mathematics, the "Académie des Beaux Arts" for the fine arts, and the "Académie des Sciences Morales et Politiques" for mental philosophy and jurisprudence. It is not a question of altering the essential character of the Royal Society, as an integral one: it would be only a natural development of its organisation if its members were allowed to constitute themselves into sections for physics, mathematics, philosophy, history, and philology.

Physical and Mathematical Science, however, engages the labour of six other learned societies. There are the Astronomical Society with 528 members, the Chemical with 518, the Meteorological with 306, and the Geological with 1,204 members. We have also a Statistical Society with 371 members, and a Mathematical with 111. Collectively, these form seven societies, with 3,638 members, giving, in relation to the population of the United Kingdom, 1·21 in every 10,000 either a physicist or a mathematician in the highest sense. The next group of societies comprises those engaged in the advancement of the science of life, whether vegetable or animal. Biology is a favourite study, and many are intensely devoted in exploring the many problems which are taxing the mind of the philosopher and moralist. Connected with Vegetable Physiology are the Linnean Society with 482 members, the Botanic with 2,420, the Horticultural with 3,595, and the Agricultural with 5,500 members. And connected with Animal Physiology are the Zoological with 2,920 members, the Entomological with 208, the Ethnological with 219, and the Anthropological with 1,031 members; in all eight societies, having in the aggregate 16,300 members. It must be remembered, however, that the largest of these societies have their Gardens and Exhibitions, which attract numerous members, and it would demand an excess of charity to regard all the members in this group as strictly men of science. Archæology has numerous votaries. There is the Society of Antiquaries, the oldest of our scientific societies, founded nearly 300 years ago, in 1572, having now 651 members, but the number of fellows was in 1862 restricted to 600. We have also a British Archæological Institute with 697 members, and an Archæological Association with 484 members, besides a very large number of other archæological societies. Then comes the Geographical with its 2,150 members, the most popular of societies, owing much to its illustrious president, Sir Roderick Murchison, and still more to the great contributions to geographical science by Livingstone, Speke, Grant, and Baker. And next we find the large group of societies for the Promotion of Applied Science. There is the Society for the Encouragement of Art, Manufacture, and Commerce, so elastic, so active, and so enterprising, having 3,200 members; the Institute of Civil Engineers with 1,700 members, and the Institute of British Architects with 498 members, each of them comprising men engaged in active life, yet deeply interested in the advancement of science. Of a more miscellaneous character are the Microscopical Society with 360 members, the Philological with 200, the Numismatic with 160, the Asiatic with 320 members, and the United Service Institution with 3,800 members. And, besides these, there are the Royal and London Institutions, the British Association, and Social Science Association, each having its thousands of members, to say nothing of the medical societies, and the numerous scientific societies and philosophical institutions in all the leading towns.

Were all who in London and the provinces are associated for the promotion of science carefully calculated, we should find that there are now about 120 learned societies, with an aggregate of 60,000 members; and deducting from the number at least one-fourth for members who belong to more than one society, we arrive at the interesting fact that there are, in the United Kingdom, 45,000 men representing the scientific world, or in the proportion of fifteen in every ten thousand of the entire population; the "upper ten thousand" of the aristocracy of learning being thus three times as many as the "upper ten thousand" of the aristocracy of wealth. But are we satisfied with the result? Are all the societies equally active in encouraging the pursuit of science? Are their terms of admission too loose or too narrow? Without entering into the internal management of our learned societies, we might wish for a fuller and earlier publication of their transactions, for the collection of more complete technical libraries, properly catalogued and classified, and for a better action in the way of granting tokens of recognition to successful discoverers and investigators of the great arcana of Nature.

Within the last twenty years, at least half as many new societies have been formed for the promotion of science, and evidences are not wanting to show that an enormous stimulus has been given to science in every direction. In the number of scientific works published, and in the circulation which they have had; in the variety of scientific journals started and successfully maintained; in the respect paid to Science—ay, in the very popularity which greets Science, wherever it exhibits itself, we see abundant reason for congratulation. A brilliant future opens itself for the cultivation of science. Happy will it be when "many shall run to and fro, and knowledge shall be increased;" happy when men will realise that "pleasure is a shadow, wealth is vanity, and power a pageant; but knowledge is ecstatic in enjoyment, perennial in fame, unlimited in space, and infinite in duration." Truly, in the performance of this sacred office the man of science "fears no danger, spares no expense, looks in the volcano, dives into the ocean, perforates the earth, wings his flight into the skies, enriches the globe, explores sea and land, contemplates the distant, examines the minute, comprehends the great, ascends to the sublime, no place too remote for his grasp, no heaven too exalted for his reach."

LEONE LEVI

THE DEPTHS OF THE SEA

THE opening meeting of the Royal Society on Thursday last was attended by a numerous assemblage of men of science, especially attracted by the announcement that Dr. Carpenter, representing a committee consisting of Professor Wyville Thomson, Mr. Gwyn Jeffreys, and himself, would communicate the results of the deep-sea dredging explorations, carried out in the course of the past summer and autumn in the *Porcupine*, a vessel expressly fitted out and placed by the Government at the disposal of the committee for this purpose.

At the conclusion of Dr. Carpenter's lucid exposition, which was necessarily but a mere *résumé* of the report itself, it appeared quite evident that rumour had not at all exaggerated the scientific value of these explorations, for it is not too much to say that the results of this expedition must be classed with the most important which of late years have been brought before the notice of the scientific world.

More than a quarter of a century ago, the late Edward Forbes, one of the first naturalists who took the common oyster dredge from the hands of the fisherman to convert it into an instrument for extended scientific research, after employing it in the commencement along the shores of his native little Isle, and subsequently in the seas surrounding the British Islands, and in other parts of Europe, found, upon comparing his observations, that there appeared to be evidence in favour of the existence of a succession of natural zones of marine life according to depth, which zones, however, seemed to become more and more sterile in organisms in descending order; until at last it suggested itself that a zone might be arrived at, at a depth roughly estimated as exceeding 300 fathoms from the surface, containing but sparse traces of organic life, or even such an one as might be entitled to the appellation of Azoic.

This latter hypothesis was brought forward by him as a suggestion worthy of consideration, and not as a dogma or established principle, as he was fully aware that in the dredging explorations which he had been able to carry out up to that time, he had never reached so great a depth as even 300 fathoms, below which the sea-bottom was inferred to be comparatively or altogether sterile; on the contrary, whilst advancing the conclusions which seemed to be but natural deductions from the data then at his disposal, he continually kept pointing out that whether such an hypothesis was correct or not, it was of the highest importance to science to prosecute these researches further, so as to ascertain the true nature of the deep-sea bottom, for, to use his own words in his "History of the European Seas," "it is in its exploration that the finest field for marine discovery still remains."

Before the author of this suggestion had time or opportunity for carrying out such explorations as would have verified or disproved his hypothesis, he was unfortunately cut off by an early death; whilst the hypothesis, in the state in which he had left it, was without further investigation eagerly grasped at and accepted by men of science, both at home and abroad, for the special reason that it appeared to afford a simple explanation of various phenomena which had long remained enigmas to both palæontologists and geologists; as, for example, amongst others the occurrence, in various periods of the earth's history, of vast accumulations of sedimentary strata apparently altogether devoid of organic remains.

Although this hypothesis, when somewhat modified, may possibly be found to hold good in respect to certain forms and conditions of life, the results of some casts of the dredge made in depths of from 270 to 400 fathoms in Sir James Ross's Antartic Expedition, and subsequently, the deep-sea soundings described by Dr. Wallich as made in 1860, in the *Bulldog*, in vastly greater depths, demonstrated quite conclusively that it could no longer be retained as a generalisation.

It now appears strange to look back and observe what very little notice was taken of these new data; more especially of the important researches of Dr. Wallich on the North Atlantic sea-bed, which for years, if not all but overlooked, certainly do not appear to have received from zoölogists the full credit which they undoubtedly deserved: geologists and palæontologists were evidently loth to abandon an hypothesis which in many respects suited their requirements.

However long truth may remain dormant, it must eventually assert itself in science as in all other matters, and the advancing strides of Biology and Geology soon demanded that such problems should be definitely and conclusively solved, and that the depths of the sea also should be carefully searched for the missing links of evidence requisite to complete their respective chains of reasoning. This was not felt to be the case in England alone; already in Scandinavia we find the *savants* of Norway and Sweden working with their slender means in the right direction, and assisted by their Governments with a hearty good-will and determination which could not fail to ensure valuable results, such as have already been brought forward by Sars, Nordenschjold, Torrell, and others.

In England, men of science, equally impressed with the importance of this inquiry, wished, with an honourable pride, to see that the country which had so long claimed the empire of the sea, should, in a question of so purely marine investigation, do something worthy of herself; and, being fully alive to the impossibility of doing so without the aid of the Government, applied themselves first to the task of procuring such assistance. Since it is an acknowledged but melancholy fact, that science does not in England either obtain the high position in society, or the influence with the ruling powers of the country which is accorded to it on the Continent in general, it is a subject for congratulation that the urgent appeals made to the Government should have in this instance proved so successful; and after the Government had provided the ships and equipment necessary for the expeditions of last year and this, it is a further subject for congratulation that the direction of these scientific explorations should have been entrusted to such able men as Dr. Carpenter, Prof. Wyville Thomson, and Mr. Gwyn Jeffreys, who constitute the present committee.

The expedition of last year being the first of its kind, had, as might be anticipated, many difficulties to contend with; the ship itself, besides starting at a late season of the year, was ill suited to the undertaking, was provided with but extremely inefficient winding machinery, imperfect appliances and instruments, and moreover, the observers and their assistants had, as it were, to serve an apprenticeship in the management of such operations.

This year, besides being fortunate in securing unusually favourable weather during the major part of the operations, all the above-mentioned difficulties had been provided against; whilst, at the same time, the experience gained during the last year's cruise contributed very greatly to the complete success of the expedition as a whole.

As yet, it would be premature to attempt any description of the results of these explorations, for the Report which was commenced at the meeting of the Royal Society last Thursday is not yet concluded, but is to be continued at its next meeting; sufficient, however, has been already brought forward to prove satisfactorily the great importance of the data obtained to science in general. Besides corroborating, and in some respects correcting the conclusions deduced from the operations of the last year's expedition, many new facts and observations have been collected, whilst the supply of specimens and materials for examination which have been brought home will no doubt give full occupation to the members of the committee for some time to come, besides obliging them to bring to their assistance the services of the physicist, chemist, and mineralogist, each in their several departments.

The practicability of exploring even the deepest portions of the ocean bed may now be considered to be fully established; the conclusive proofs brought forward showing the existence of warm and cold areas of the deep-sea bottom, in close proximity to one another, each inhabited by its distinct and characteristic fauna, is as surprising as it is important in its scientific bearings, and particularly in its relations to geology and palæontology; whilst the investigations into the temperature of the different ocean zones, and the nature of the gases contained in the sea-water at various depths, are intensely interesting and suggestive.

The question as to the existence of an azoic ocean zone at *any* depth, must now be regarded as finally settled in the negative. The hypothesis which appeared to Edward Forbes to be warranted by all the data which the science of his day could supply, must now be abandoned; it is certain, however, that all who knew him will do his memory the justice of believing that, were he now alive, so far from regretting the necessity of withdrawing a suggestion which appeared to explain several important points in science now once more involved in obscurity, he would have been the first of the converts to the views now proved to be more correct, and the first to congratulate the members of the deep-sea dredging committee upon so successful and brilliant a termination of their labours.

David Forbes

PHYSICAL METEOROLOGY

I.—ITS PRESENT POSITION

It is a well-known remark of the historian of science that our progress in astronomy has been made in exact accordance with certain laws which regulate the advancement of knowledge. Neither the march of the sun by day, nor that of the moon by night, is more rigidly surrounded and circumscribed by law than the march of that intellect which has successfully interpreted celestial motions.

We had first of all an observing age. Thousands of years ago in the plains of the East we had astronomers who, albeit with imperfect instruments, lacked neither zeal nor intelligence in their nightly study of the stars. Many of their theoretical ideas were untenable, nay, even absurd, but yet they served to bind together into a formal law the mass of observations which their nightly industry collected.

And so step by step our knowledge of celestial motions progressed, until it culminated in the discoveries of Copernicus and Kepler; and we were presented at last with a bird's-eye view of the solar system, taken, as it were, from without, in which that which appears to be, finally gave place to that which is. Thus the first stage was passed, and astronomers had now another question to put to the universe: it was no longer What are the real motions of the planets? but rather, Why do they move in orbits which we know to be ellipses having the sun in one of the foci? Hardly had this question been put, when a great genius answered it. The immortal Newton told us that the same law which regulates the motions of the planets round the sun, and that of the moon round the earth, determines also the path of a stone thrown by the hand, or the velocity of an apple falling from a tree.

One law was shown to hold throughout, and the expression of that law having been obtained, we were easily led to the third stage in the development of astronomy.

The problem was now—from our knowledge of the present places and motions of the heavenly bodies, and of the laws which regulate these, to determine their future places. In fact, the last or prophetical stage of the science had now been reached, and accordingly we had a race of prophets who compiled our nautical almanacs, culminating in two great prophets—one French and one English—who told us where to look for Neptune.

Thus in the most complete branch of physical inquiry there have been three stages of development. We have, first, the observational stage, the object of which was to discover the real motions of the planets of our system; next, we have the stage of generalisation, assigning the mechanical laws regulating these motions; and, lastly, we have the stage of deduction, which, from a knowledge of the places and laws of motion of the heavenly bodies, predicts their future courses.

Each of these stages had its own peculiar difficulty to encounter. That in ascertaining the actual motions of the heavenly bodies consisted in the fact that our point of view is a movable one, and it was only when this had been surmounted that the true explanation was obtained. Again, the difficulty in the generalisation accomplished by Newton consisted in recognising that the planets in their orbits are subject to the same mechanical laws which regulate motions on the earth's surface, and in ascertaining and applying these laws; while, again, the difficulty in the third or deductive stage was an analytical one, for it was necessary to possess a method of analysis sufficiently powerful to calculate the motions of a set of bodies mutually attracting one another.

Now these historical facts, connected with the progress of astronomy, are of very great value to us, especially with reference to those other branches of science not so far advanced. We have, as it were, given us a standard of growth and development, and by measuring the younger child against the elder, we may be able to know the exact advancement of our latest born, and also the course of discipline best calculated to ensure a vigorous growth. It is by this astronomical standard that I now wish very briefly to measure what has been done in meteorology, and during these remarks I may perhaps venture to suggest a course of diet and discipline. But here, alas! there is little advancement to chronicle: the first stage of progress—the observational one—is yet very incomplete; for, viewing meteorology as that science which treats of the physics of the earth's surface, and more particularly of the atmosphere—its motion, and its physical properties, it must be acknowledged that these are very imperfectly known. At the same time it must be owned, that there are very serious difficulties in the way of obtaining this knowledge, more and greater perhaps than there were in obtaining the true motions of the heavenly bodies.

It is not because, as in astronomy, our point of view is a movable one; but rather that we are so mixed up with the earth and its atmosphere, and the motions of the latter are on so large a scale, that we find the greatest possible difficulty in grasping their true import. We are like a soldier in the midst of a great battle, who can give but a very poor and partial account of it, attaching, as he does, undue importance to those passages of arms with which he is most concerned, and ignorant, as he must be, of the general plan of the whole. What is wanted is a bird's-eye view of the atmosphere, such as it might appear to the inhabitants of the moon, who enjoy peculiar advantages in studying the physical features of our earth, just as we do with respect to the surface of our satellite. But there is another difficulty, at least in oceanic regions. Here the scientific worker is very much in the same position as the Jews of old when rebuilding their temple, that is to say, he must work with the one hand and fight with the other, especially when there is any great commotion going on.

The commander of a vessel during a cyclone must first of all look after his vessel, and then, if he has any time to spare, it may be devoted to his barometer and thermometer. Indeed, whether on sea or land, the grand and interesting phenomena of nature carry in their train so much that is overwhelming, that the mind of the observer is not unfrequently unfitted for calm investigation. There is still a third difficulty, and that is the great improbability (despite the perseverance and industry shown by Glaisher and other meteorologists) of ever obtaining by observation a very complete knowledge of the upper regions of the earth's atmosphere.

So much for the difficulties in the way of observing, and now one word with regard to the instrumental means at our disposal. Of late years these have been greatly improved, and one of the most notable achievements in this way is the anemometer of Dr. Robinson, by means of which we can record continuously the horizontal velocity and direction of the wind. Another is the application of photography to meteorological observations, so successfully advocated and extended by the present distinguished President of the Royal Society, by means of which we obtain a continuous record of the pressure, temperature, and hygrometric condition of the air. Again, by means of certain electrical appliances due to Sir C. Wheatstone and others we may place our instrument, whatever it be, at the top of a mountain, or at the bottom of the sea, or in some equally inaccessible region, while the record of the instrument so placed may be read in the quiet and comfort of our own studies. Thus, instrumentally we are well equipped and rapidly improving, but the observations as yet made with complete instruments are very few indeed.

I come now to a very important point. Has the best use been made of the observations already obtained? Of course we all know that there has been a deplorable want of co-operation among observers, as well as of system in making their observations; but we may hope that, through the meteorological offices and societies established in all civilised countries of the world, a greater amount of method will by degrees be obtained. There is, however, something more than all this, and

I have taken advantage of the late meeting of the British Association, at Exeter, to bring the subject before meteorologists. It appears that the general term meteorology embraces two entirely distinct subjects, one of these having reference to physiology, while the other forms a branch of physical research.

The object of the one is to study the connexion between atmospheric conditions, and the health of such organisms (animal and vegetable) as are subjected to these conditions; while the other or physical question is particularly concerned with the movements of the earth's atmosphere, and with the causes thereof.

On both of these important branches we are in almost entire ignorance. With respect to the first, the amount of vapour present in the air is without doubt a very important element of climate, inasmuch as this affects in a marked manner the skin of the human body, and the leaves of plants; but I am not aware that it has yet been determined by the joint action of naturalists and meteorologists what is the precise physical function expressing proportionally the effect of moisture upon animal and vegetable life. Is it simply relative humidity? or does not a given relative humidity at a high temperature have a different effect from that which it has when the temperature is low? There is, in fact, an absence of information as to the precise physical formula which is wished by physiologists, as expressing the effect of moisture upon organic life.

If we come in the next place to consider the physical branch of meteorology, or that which regards the motions of the earth's atmosphere, this is almost as far behind. The explanation of the trades and anti-trades is the one great generalisation which we have accomplished. Certain laws regarding cyclonic storms have lately been discovered; but to this day we are in ignorance of that exact motion of air which constitutes a cyclone, some holding that the motion is entirely rotatory, while others maintain that there is a considerable indraught of air from the circumference to the centre. Again, there is no fact better established than the diurnal movements of the barometer; but what is the motion of air or its constituents implied by them is still a point open to dispute. Now, these are both matters of fact, and there must be some reason why we know so little about them. Nothing, of course, could be known until the instrumental difficulties of the problem had been surmounted, and a suitable anemometer constructed; but now, we have good instruments, and have begun to make good observations. What, then, is the remaining drawback? I believe it is to be found in the fact that while instrumental appliances and observations have progressed, methods of reduction, which naturally lag behind observations, have not yet progressed, but are only just beginning to move. Those hitherto in use combine the physiological with the physical element,—they are a cross between the two, and are subject, I venture to say, as all such crosses are, to the general law of barrenness. Still not much time has been lost, for in the dark ages of few and bad observations it would have been useless to divide the meteorological field: meteorology, then, might be likened to one of those organisms of very low development that had just begun to exhibit the slightest possible tendency to split into two; the application of the knife would then have been premature; but now it may be used with advantage, and the one half allowed to rush into the arms of physiology, while the other seeks the embrace of physical research. In plain language, if we want to obtain physiological results we must reduce our observations with especial reference to physiology, while if physical results be desired, they must be reduced with especial reference to physical laws.

I must, however, reserve for another article a description of a method of reduction having this latter object in view.

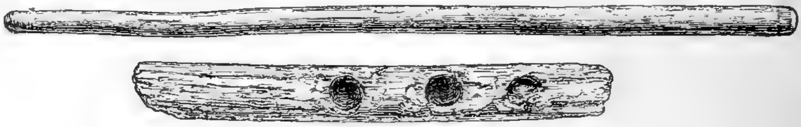
BALFOUR STEWART

PREHISTORIC TIMES

Prehistoric Times, as illustrated by Ancient Remains, and the Manners and Customs of Modern Savages. By Sir John Lubbock, Bart., F.R.S., &c. Second Edition. (London, 1869: Williams and Norgate.)

WE may be pardoned for not being cosmopolite enough to judge books without any regard to their nationality. Too often, though Englishman may have contributed much to some important subject, no systematic English treatise sums up the evidence, so that our students have to depend too much on foreign books of reference. On the present subject of prehistoric archæology, however, it is satisfactory that we have, in Sir John Lubbock's work, not only a good book of reference, but the best. Its well-known plan and argument need not be re-stated here, but it has to be pointed out that the present edition contains much important new matter, especially in the chapters relating to the Stone Age, Megalithic monuments, Cave-men, and the condition of modern savages.

It is a marked character of the recent researches in prehistoric archæology, and it is one of the reasons which justify the reception of the subject as a department of positive science, that the facts disclosed lend themselves to generalisations of a thoroughly scientific character; and that, moreover, when the generalisations are once made, new facts drop in and find their places ready. Various subjects discussed in the present work illustrate this: take, for instance, the stone-implement question. The finding of flakes, scrapers, spear-heads, &c. in different parts of the world, justified a general surmise that the Stone Age had once prevailed in all inhabited districts. A few years ago, however, there were regions whence stone implements seemed hardly forthcoming. India appeared to have none, but when properly looked for they proved abundant, as witness Mr. Bruce Foote's paper in the Transactions of the Norwich Congress of 1868. Africa also seemed almost outside the Stone Age world; but now the finding of stone implements in South Africa, and even legends of their use, give the primal Stone Age possessions there as elsewhere. No sooner, too, were the rude implements of the Drift type thoroughly recognised in the valley of the Somme, than it came into notice that such had long before been collected in England without knowledge of their special importance; and now Spain and India, and other districts, furnish specimens which come under the same class. So it was with the art of fire-making by friction of pieces of wood. Over most of the world, savage or civilised, the traces of its early prevalence were sufficient to justify its being generalised on as one of man's primitive arts. But there were some exceptional cases, as in Tasmania, where the natives were said to have had no means of producing fire before their acquaintance with Europeans, but to have only carried lighted brands from place to place. Sir John Lubbock, however, is now able to give (p. 440) a drawing of a Tasmanian fire-drill. It is just like the well-known instrument of Australia, Africa, and America.



TASMANIAN FIRE DRILL.

So again, in a less degree, with those rude stone menhirs, cromlechs, kistvaens, &c., which are classed under the head of Megalithic monuments. The range over which these interesting structures are found has been continually extending to new districts. Dr. Hooker's account, in his Himalayan Journals, of the modern setting up of Megalithic structures by indigenous tribes in India, received for years little notice, but has now become one of the leading facts of prehistoric archæology. As may especially be seen in Meadows Taylor's recent paper in the Journal of the Ethnological Society, monuments like our own Kit's Coty House, or Dance Main, are known in vast numbers in India, and are made the subject of careful study. A group from the reduced plate in Sir John Lubbock's work (p. 120) is given here.

MEGALITHIC STRUCTURES IN INDIA.

Was the civilisation of the lower races spread from a single centre, or from many? Is the correspondence of savage culture the result of common inheritance, or independent similar invention? This still most obscure problem is intimately connected with the evidence brought forward in Sir John Lubbock's generalisations, and especially with his details of modern savage tribes as representatives of older strata of prehistoric man. The point is one which especially strikes those who notice the surprising similarity of the implements of the lower races in the most different regions, as where, in the present work, three all but identical arrow-heads from modern North and South America and ancient France, are set side by side (p. 99); or modern savage flint scrapers are figured, undistinguishable from those of remote European antiquity. Sir John Lubbock insists with much force (p. 545) on the consideration that this similarity is due especially to similarity of materials; that the pointed bones used for awls are necessarily similar everywhere, that obsidian knives from Mexico are like the flint knives of our own country, not so much because the ancient Briton resembled the Aztec, as because the fracture of flint is like that of obsidian. And his remark (p. 121), that any child with a box of bricks will build dolmens and triliths is a highly reasonable protest against those antiquaries who interpret the similarity of Megalithic structures in different districts as proof that their builders were of kindred race.

With regard to a most interesting topic treated of by Sir John Lubbock, that of the existence of savage tribes destitute of religion, I am disposed to entertain a view different from his. To a great extent, indeed, our difference is rather nominal than real. He adopts a definition of religion more stringent than I do, and thus excludes from the catalogue of religious tribes many which on the same evidence I should include. Dieffenbach's evidence, for instance, is quoted as follows (p. 556): "If we take religion in its common meaning, as a definable system of certain dogmas and prescriptions, the New Zealanders have no religion. Their belief in the supernatural is confined to the action and influence of spirits on the destiny of men, mixed up with fables and traditions." This, from my point of view, is an admission that the New Zealanders have a religion; and, indeed, we know that they are strong believers in a future existence, and regard the names of their ancestors as tutelary spirits. Moreover, the assertions of travellers on this point not seldom break down on closer scrutiny. Thus mention is made here of a statement in the *Voyage de l'Astrolabe* that the Samoans have no religion; but the explorers' information was evidently insufficient, and an elaborate account of the Samoan deities, priests, temples, prayers, sacrifices, may be found in Turner's "Polynesia." Among Sir John Lubbock's list of evidence there are, indeed, cases which cannot be thus easily met. But while admitting theoretically that a state without religion may have prevailed among early tribes of men, and may still be represented by surviving savages, I fail to find as yet any indisputable case.

TERRA-COTTA URN FROM ALBANO

Among the special points of interest introduced in the present volume, it may be mentioned that the habitations men lived in during the Bronze Age are displayed in a very interesting way, in imitative terra-cotta urns of the period, such as this from Albano. We must probably go many ages back from the date of the Italians of the Bronze Age, who dwelt in these neat huts, to the date of the rude Stone Age cave-men of Central France, the contemporaries of the reindeer and the mammoth, which they delineated with such remarkable artistic vigour. One of these people's interesting drawings (p. 324) is given here, representing a snake or eel, two horses' heads, and a human figure (which Lord Monboddo would probably have claimed as special evidence). This may possibly be the earliest known portrait of man.

STONE-AGE SCULPTURES

The advocates of the theory that savages are degenerate descendants of civilised men, have still full scope in pointing out the imperfections of their adversaries' evidence and argument. But the new facts, as they come in month by month, tell steadily in one direction. The more widely and deeply the study of ethnography and prehistoric archæology is carried on, the stronger does the evidence become that the condition of mankind in the remote antiquity of the race is not unfairly represented by modern savage tribes.

E. B. TYLOR.

THE ORIGIN OF SPECIES CONTROVERSY.

Habit and Intelligence, in their Connection with the Laws of Matter and Force. A Series of Scientific Essays. By Joseph John Murphy. (Macmillan and Co., 1869.)

I.

THE flood of light that has been thrown on the obscurest and most recondite of the forces and forms of Nature by the researches of the last few years, has led many acute and speculative intellects to believe that the time has arrived when the hitherto insoluble problems of the origin of life and of mind may receive a possible and intelligible, if not a demonstrable, solution. The grand doctrine of the conservation of energy, the all-embracing theory of evolution, a more accurate conception of the relation of matter to force, the vast powers of spectrum analysis on one side, showing us as it does the minute anatomy of the universe, and the increased efficiency of the modern microscope on the other, which enables us to determine with confidence the structure, or absence of structure, in the minutest and lowest forms of life, furnish us with a converging battery of scientific weapons which we may well think no mystery of Nature can long withstand. Our literature accordingly teems with essays of more or less pretension on the development of living forms, the nature and origin of life, the unity of all force, physical and mental, and analogous subjects.

The work of which I now propose to give some account, is a favourable specimen of the class of essays alluded to, for although it does not seem to be in any degree founded on original research, its author has studied with great care, and has, in most cases, thoroughly understood, the best writers on the various subjects he treats of, and has brought to the task a considerable amount of original thought and ingenious criticism. He thus effectually raises the character of his book above that of a mere compilation, which, in less able hands, it might have assumed.

The introductory chapter treats of the characteristics of modern scientific thought, and endeavours to show, "that the chief and most distinctive intellectual characteristic of this age consists in the prominence given to historical and genetic methods of research, which have made history scientific, and science historical: whence has arisen the conviction that we cannot really understand anything unless we know its origin; and whence also we have learned a more appreciative style of criticism, a deeper distrust, dislike, and dread, of revolutionary methods, and a more intelligent and profound love of both mental and political freedom." The first six chapters are devoted to a careful sketch of the great motive powers of the universe, of the laws of motion, and of the conservation of energy. The author here suggests the introduction of a useful word, *radiance*, to express the light, radiant heat, and actinism of the sun, which are evidently modifications of the same form of energy,—and a more precise definition of the words *force* and *strength*, the former for forces which are capable of producing motion, the latter for mere resistances like cohesion.

He enumerates the primary forces of Nature as, gravity, capillary attraction, and chemical affinity, and notices as an important generalisation "that *all primary forces are attractive;* there is no such thing in Nature as a primary repulsive force" (p. 43). Now here there seem to be two errors. Cohesion, which is entirely unnoticed, is surely as much a primary force as capillary attraction, and, in fact, is probably the more general force, of which the other is only a particular case; and elasticity is the effect of a primary repulsive force. In fact, at p. 26, we find the author arguing that *all matter is perfectly elastic*, for, when two balls strike together, the lost energy due to imperfect elasticity of the mass is transferred to the molecules, and becomes heat. But this surely implies repulsion of the molecules; and Mr. Bayma has shown, in his "Molecular Mechanics," that repulsion is as necessary a property of matter as attraction.

The eighth chapter discusses the phenomena of crystallisation; and the next two, the chemistry and dynamics of life. The reality of a "vital principle" is maintained as "the unknown and undiscoverable something which the properties of mere matter will not account for, and which constitutes the differentia of living beings." Besides the formation of organic compounds, we have the functions of organisation, instinct, feeling, and thought, which could not conceivably be resultants from the ordinary properties of matter. At the same time it is admitted that conceivableness is not a test of truth, and that all questions concerning the origin of life are questions of fact, and must be solved, not by reasoning, but by observation and experiment; but it is maintained that the facts render it most probable that "life, like matter and energy, had its origin in no secondary cause, but in the direct action of creative power." Chapters X. to XIV. treat of organisation and development, and give a summary of the most recent views on these subjects, concluding with the following tabular statement of organic functions :—

Formative or Vegetative Functions, essentially consisting in the Transformation of Matter.

Chemical	Formation of organic compounds.
Structural.	Formation of tissue.
	Formation of organs.

Animal Functions, consisting essentially in the Transformation of Energy.

Motor.	Spontaneous.
	Reflex.
	Consensual.
	Voluntary.
Sensory.	Sensation.
	Mind.

In the fifteenth chapter we first come to one of the author's special subjects,—the Laws of Habit. He defines habit as follows : "The definition of habit and its primary law, is that all vital actions tend to repeat themselves ; or, if they are not such as can repeat themselves, they tend to become easier on repetition." All habits are more or less hereditary, are somewhat changeable by circumstances, and are subject to spontaneous variations. The *prominence* of a habit depends upon its having been recently exercised ; its *tenacity* on the length of time (millions of generations it may be) during which it has been exercised. The habits of the species or genus are most tenacious, those of the individual often the most prominent. The latter may be quickly lost, the former may appear to be lost, but are often latent, and are liable to reappear, as in cases of reversion. The fact that active habits are strengthened, while passive impressions are weakened, by repetition, is due in both cases to the law of habit; for, in the latter, the organism acquires the habit of not responding to the impression. As an example, two men hear the same loud bell in the morning ; it calls the one to work, as he is accustomed to listen to it, and so it always wakes him ; the other has to rise an hour later, he is accustomed to disregard it, and so it soon ceases to have any effect upon him. Habit has produced in these two cases exactly opposite results. Habits are capable of any amount of change, but only a slight change is possible in a short time ; and in close relation with this law are the following laws of variation.

Changes of external circumstances are beneficial to organisms if they are slight ; but injurious if they are great, unless made gradually.

Changes of external circumstances are agreeable when slight, but disagreeable when great.

Mixture of different races is beneficial to the vigour of the offspring if the races mixed are but slightly different ; while very different races will produce either weak offspring, or infertile offspring, or none at all. Even the great law of sexuality, requiring the union of slightly different individuals to continue the race, seems to stand in close connection with the preceding laws.

The next seven chapters treat of the laws of variation, distribution, morphology, embryology, and classification, as all pointing to the origin of species by development ; and we then come to the causes of development, in which the author explains his views as follows :—

> These two causes, self-adaptation and natural selection, are the only *purely physical* causes that have been assigned, or that appear assignable, for the origin of organic structure and form. But I believe they will account for only part of the facts, and that no solution of the questions of the origin of organization, and the origin of organic species, can be adequate, which does not recognise an Organising Intelligence, over and above the common laws of matter. . . . . But we must begin the inquiry by considering *how much* of the facts of organic structure and vital function may be accounted for by the two laws of self-adaptation and natural selection, before we assert that any of those facts can only be accounted for by supposing an Organising Intelligence.

Again :

> Life does not suspend the action of the ordinary forces of matter, but works through them. I believe that wherever there is life there is intelligence, and that intelligence is at work in every vital process whatever, but most discernibly in the highest. . . . Nutrition, circulation, and respiration are in a great degree to be explained as results of physical and chemical laws ;—but sensation, perception, and thought cannot be so explained. They belong exclusively to life ; and similarly the organs of those functions—the nerves, the brain, the eye, and the ear—can have originated, I believe, solely by the action of an Organising Intelligence.

Admitting Mr. Herbert Spencer's theory of the origin of the vascular system, and possibly of the muscular, by self-adaptation, he denies that any such merely physical theory will account for the origin of the special complexities of the visual apparatus :

> Neither the action of light on the eye, nor the actions of the eye itself, can have the slightest tendency to produce the wondrous complex histological structure of the retina ; nor to form the transparent humours of the eye into lenses ; nor to produce the deposit of black pigment that absorbs the stray rays that would otherwise hinder clear vision ; nor to produce the iris, and endow it with its power of closing under a strong light, so as to protect the retina, and expanding again when the light is withdrawn ; nor to give the iris its two nervous connections, one of which has its root in the sympathetic ganglia, and causes expansion, while the other has its root in the brain and causes contraction.

Nor will he allow that Natural Selection (which he admits may produce any simple organ, such as a bat's wing) is applicable to this case ; and he makes use of two arguments which have considerable weight. One is that of Mr. Herbert Spencer, who shows that in all the higher animals natural selection must be aided by self-adaptation, because an alteration in any part of a complex organ necessitates concomitant alterations in many other parts, and these cannot be supposed to occur by spontaneous variation. But in the case of the eye he shows that self-adaptation cannot occur, whence he conceives it may be proved to be almost an infinity of chances to one against the simultaneous variations necessary to produce an eye ever having occurred. The other argument is, that well-developed eyes occur in the higher orders of the three great groups, Annulosa, Mollusca, and Vertebrata, while the lower orders of each have rudimentary eyes or none ; so that the variations requisite to produce this wonderfully complicated organ must have occurred three times over independently of each other. In the first of these objections, he assumes that many variations must occur simultaneously, and on this assumption his whole argument rests. He notices Mr. Darwin's illustration of the greyhound having been brought to its present high state of perfection by breeders selecting for one point at a time, but does not think it possible "that any apparatus, consisting of lenses, can be improved by any method whatever, unless the alterations in the density and the curvature are perfectly simultaneous." This is an entire misconception. If a lens has too short or too long a focus, it may be amended *either* by an alteration of curvature, or an alteration of density; if the curvature be irregular, and the rays do not converge to a point, then any increased regularity of curvature will be an improvement. So the contraction of the iris and the muscular movements of the eye are neither of them essential to vision, but only improvements which might have been added and perfected at any stage of the construction of the instrument. Thus it does not seem at all impossible for spontaneous variations to have produced all the delicate adjustments of the eye, once given the rudiments of it, in nerves exquisitely sensitive to light and colour; but it does seem certain that it could only be effected with extreme slowness; and the fact that in all three of the primary groups, Mollusca, Annulosa, and Vertebrata, species with well-developed eyes occur so early as in the Silurian period, is certainly a difficulty in view of the strict limits physicists now place to the age of the solar system. A. R. WALLACE

THE PLANTS OF MIDDLESEX

Flora of Middlesex: a Topographical and Historical Account of the Plants found in the County; with Sketches of its Physical Geography and Climate, and of the Progress of Middlesex Botany during the last Three Centuries. By Henry Trimen, M.B., F.L.S., and W. T. Thiselton Dyer, B.A. Pp. xli., 428. (London: Hardwicke, 1869.)

THE first local Flora published in England gives a list of the plants of Hampstead Heath. It was prepared by Thomas Johnson, Apothecary on Snow Hill. Early on the morning of the 1st August, 1629, and accompanied by a few friends, he left London and proceeded on a simpling expedition to Hampstead, by way of Kentish Town and Highgate. A heavy shower arrested their progress for a little, but nothing daunted they made their way into the woods, and then on to the heath. The day's excursion was brought to a close in a country inn at Kentish Town, where the party dined together.

Johnson enumerated seventy-two plants as the result of the day's simpling. In subsequent expeditions he added sixty-nine others, so that in 1632 his *Enumeratio Plantarum in Ericeto Hampsted. cresc.* contained 141 species. This rare little volume, with its forgotten names—those of Gerarde and Lobel—is the earliest precursor of the Flora of Middlesex. Since its publication, the materials have been gradually accumulating for illustrating the Flora of the Metropolitan district, and one of the most valuable features in the work before us is, that its authors have, with great care and singular success, investigated and expounded all the ancient as well as the more recent plant-lore bearing on the subject.

The bi-nominal system of nomenclature and the Linnean classification introduced, somewhat more than a century ago, a new era into the science of Botany, and relegated to comparative obscurity the older authors. The difficulty of determining the value of their names, and the practice of neglecting all ante-Linnean synonymy, have caused their labours to be set aside. The authors of this volume have made the works of these earlier writers critically certain by the help of the Herbaria of Merrett, Petiver, Plukenet, Ray, and specially of Buddle, and of the manuscripts relating to them now preserved in the British Museum.

We have here given for the first time an authentic biography, so to speak, of the different plants so far as they are connected with Middlesex. The name of the observer who first recorded each plant, the date of the record, and the place where it was observed, are specified; while the chronologically-arranged localities where it has been at different times gathered, enable one frequently to trace its increasing rarity, and in not a few cases the biography terminates with the record of its complete extirpation. Thus Turner, the father of British Botany, first (1562) records Penny-royal (*Mentha Pulegium*, Linn.) from "beside Hundsley upon the Heth beside a watery place;" after him Gerarde (1597) tells us that it grew "on the common neere London called Miles ende, whence poore women bring plentie to sell in London Markets;" and then, through Blackstone, to our own time when it was found in plenty beside the Hampstead ponds, but finally disappeared from the county about twenty years ago. London Rocket, which Morison says might have been reaped like a crop of wheat on the ruins near St. Paul's after the Great Fire, was, up to the beginning of the present century, a common plant in Middlesex, but is now completely lost. The history of *Cucubalus*, from the Isle of Dogs, is much shorter. Known in England only in this locality, it flourished apparently in a wild state for twenty years, until building operations destroyed the habitat about twelve years ago.

Every page of the volume supplies similar interesting details in the history of Middlesex plants. This feature of the work is as novel as it is important. There is abundant evidence that the authors, in addition to their faithful and even loving exposition of the labours of their predecessors, possess a sound critical acquaintance with the species of British plants. Even in this aspect, the volume is not behind the best of our county Floras.

The influence of the geological condition of a district upon the organised bodies connected with it has lately been receiving the attention it deserves. Important conclusions have resulted from the Government inquiry into the relations subsisting between the diseases of man and the geological structure of the south-eastern corner of England. The connection between the indigenous vegetation and the geology of its habitat is not less interesting, and, when data have been sufficiently accumulated to warrant safe deductions, will yield valuable information. M. Thurmann, in an elaborate essay on the botany of the Jura, has shown that vegetation is influenced by the manner in which the particles of the rocks are combined, rather than by the nature of the materials of which they are composed. He has consequently classified rocks into two great groups, based on their mechanical constitution: the one he calls "Eugéogènes" (plentiful-detritus-yielding) and the other "Dysgéogènes" (sparing-detritus-yielding). The essential differences between the two groups are in respect to their hardness, their power of absorbing and retaining moisture in small masses, their permeability in extensive deposits, and the rate at which they form detritus resulting from the possession of these characteristics. Mr. Baker has applied the conclusions of the French botanist to Britain, in his Flora of North Yorkshire, and, more recently, in that of Northumberland and Durham. The limited extent of Middlesex, and the uniform character of its geology, give little scope for the application of these views to its Flora. The only Dysgeogenous rocks are the narrow outcrop of chalk in the north and north-west; the remainder of the county being composed of typical Eugeogenous strata. As far as it is possible, however, the authors have made good use of M. Thurmann's labours, and the limited application is to some extent compensated for by the accuracy of the details.

Appended to the volume is a valuable contribution to the history of British botany, covering to some extent the ground taken up by Pulteney in his "Sketches," and continuing it to the present day as far as the matter relates to Middlesex. Large additions are made to Pulteney's biographies of Turner, Johnson, Plukenet, Petiver, and Doody. New and interesting memoirs are given of Buddle, Blackstone, Curtis, and other less known investigators of Middlesex plants. It would be greatly to the advantage of science, if the authors, encouraged by the success which has attended their investigations into the progress of Middlesex botany, would continue their researches, and give us, not a new edition of Pulteney, but a new History of Botany in Britain.

W. CARRUTHERS

OUR BOOK SHELF

Van Heurck on the Microscope.—*Le Microscope, sa Construction, son Maniement, et son Application aux Etudes d'Anatomie végétale.* Henri van Heurck. 8vo. pp. 223, with Illustrations, price 3*s.* (Antwerp, 1869. London: Williams and Norgate.)

THE title-page of this little work, a mere fragment of which we have transcribed above, is perhaps its most objectionable feature. The ambitious superscription, however, need not affect its usefulness as an elementary descriptive treatise, and the English reader may add to his information by the perusal of a manual of microscopical manipulation written from a French or Belgian standpoint.

We have no manual in English of precisely similar scope and intention with which to compare M. van Heurck's; the one which it most resembles is, perhaps, Mr. Currey's translation of Dr. Schacht's excellent guide to the use of "the Microscope in Vegetable Physiology," the chief difference being in point of thoroughness: the former is a popular, the latter a scientific work.

M. van Heurck's book is divided into two portions, of about one hundred pages each: the first, on the construction and choice of a microscope; the second, on its application to vegetable anatomy. We may describe each section in a few words.

Naturally, the instruments of French makers have prominence assigned to them; and most of the well-known models manufactured by Hartnack, Chevalier, and Nachet are figured, together with one or two modifications we do not recollect having seen before. In too many of these, cheapness and simplicity go hand in hand with toy-like inefficiency. Some are of more interest, such as Chevalier's "Universal Microscope," and a "vertical," or rather "inverted," arrangement constructed by M. Nachet for photographic purposes. In the section devoted to manipulation, the subject of micro-photography is treated at greater length than has been customary in such works.

All notice of the microscopes of English makers appears to have been omitted in the first Edition of "Le Microscope," beyond a general intimation that their "price is exorbitant, and their complication excessive;" but, "at the request of subscribers," an appendix has been prepared to the present issue, containing a description of the instruments of Ross, R. and J. Beck, and Powell and Lealand. This seems to be written with only partial knowledge, and with very unequal justice.

The second portion of the book contains little of novelty in either fact, theory, or method. Beginners will find in it the sort of information they require to enable them to examine and mount vegetable tissues, and the numerous little woodcuts will enable them to understand the more important structures. There is also a section on the application of reagents, intended for those who have advanced a step farther in histological pursuits.

We may repeat that, though M. van Heurck's work will not bear comparison with several of our English manuals in completeness, the reader will scarcely rise from it without having gained a few useful hints.

H. B. BRADY

Bryologia Silesiaca. Von Dr. Julius Milde, Professor in Breslau. (Leipzig, 1869.)

THIS is a systematic description of the mosses, not only of Silesia, but also of Jutland, Holland, the Palatinate, Baden, Franconia, Bohemia, Moravia, and the neighbourhood of Munich. Special attention is, however, devoted to the Silesian flora. The work is prefaced by an account (for the use of beginners) of the most important organs of the musci in reference to the determination of species.

New Batrachians.—*Ueber neue und wenig bekannte Batrachier aus Australien und America.* Von W. Keferstein, Prof. in Göttingen. (Berlin, 1868.)

THE Göttingen Museum is rich in Australian frogs. Prof. Keferstein here describes, from the museum specimens, twenty-nine species. He also enumerates nineteen others, recorded as such in the literature of batrachiology, although their specific value appears, in many cases, to be doubtful. The frog-fauna of Australia, according to Prof. Keferstein, bears a great resemblance to that of South America. Some batrachians from Costa Rica are likewise described in this brochure. Five plates of figures are appended. It may be worth mentioning that the authorities of the museum will be glad to exchange some of their superfluous Australian species for other batrachians.

The Sandwich Islands.—*Ein Jahr auf den Sandwich-Inseln (Hawaiische-Inseln).* Von Dr. J. Bechtinger. (Wien, 1869.)

THE chief interest of this volume lies in its pictures of the social and moral condition of a primitive people in close contact with modern civilisation, and the subject for many years of unexampled missionary efforts. The author enters somewhat fully into the character of the climate, the nature of prevalent diseases, the physical and psychical characters of the people, and their probable ethnic affinities. Leprosy is a disease unfortunately very prevalent among the inhabitants, and their Government have hit upon a notable plan for putting the sufferers out of sight, and preventing the spread of the disease by contagion. In the island of Molokai there is a plain near the sea, and walled off from the rest of the island by mountains from two to four thousand feet high, and almost totally inaccessible. To this spot lepers are conveyed by a vessel which periodically leaves Honolulu for that purpose, and for the purpose of carrying food. Every other communication with the sufferers is strictly prohibited. Dr. Bechtinger had a very natural desire to visit this forbidden valley, and ascertain the condition of its inhabitants. Knowing, however, that great opposition would be made to his doing so, he resolved to go thither privately, and attempt to reach the valley over the mountain range at its back. Attended by a photographer, he succeeded in his project, and found the poor wretches (hundreds and hundreds of them) in a most horrible state, utterly neglected and almost entirely without the necessaries of life. It is satisfactory to know that the representations of the Italian doctor in the Honolulu newspaper procured for these outcasts some amelioration of their lot, although it procured for himself abuse and ill-will. As a frontispiece to the volume there is a woodcut, reproduced from a photograph, of the author surrounded by some of the lepers of Molokai. Other woodcuts are likewise given; but they are chiefly, if not solely, remarkable for their very primitive and inartistic character.

Chemical Lessons.—*Leçons de Chimie.* Deuxième edition. Par M. Alfred Riche. (Paris: Didot Frères, 1869.)

LIKE almost all French treatises on elementary science, M. Riche's book is clearly and concisely written, and the illustrations are perfect; but although introducing many of the newest discoveries in the science (perhaps somewhat too pointedly alluded to in the preface), M. Riche does not adopt the important new views lying at the basis of modern chemistry. He still adheres to the old equivalent notation, and therefore refuses to admit the cogency of the proofs which have carried conviction to the minds of almost all other chemists. The short historical introductions under Combustion, the Atmosphere, Dissociation, and the Atomic Theory are of interest to the student, especially an extract (p. 704) from a paper by Dumas on the history of chemical affinity since the time of Barckhausen, read before the Academy of Sciences last year.

H. E. R.

NOTES ON STALACTITES

THE mineralogist is acquainted with few objects of greater beauty than the stalactitic forms assumed by many minerals. So curious are these natural growths, that I venture to offer a few remarks upon their artificial production.

The dependent clusters which line limestone caverns are formed, as has often been explained, by the following process:—When water containing carbonate of lime oozes through a porous rock, each drop loses water and carbonic acid by evaporation. As water saturated with carbonic acid only retains 0·1 per cent. of carbonate of lime in solution, it follows that when the evaporation is continued beyond the point of saturation, carbonate of lime will be deposited. Globules of water on the roofs of limestone caverns are always covered with a thin film: this gradually thickens, and a tube is formed. This tube increases in size mainly by the deposition of carbonate of lime from water running over its surface. There are, however, many cavities containing tubes of arragonite in an horizontal position, and even of a curved form. Mr. Wallace has shown* that the growth of such stalactites has been from within outwards, the solution travelling along the self-constructed tube.

The following experiment affords a ready method of studying the somewhat rapid growth of similar forms:—Select a flat piece of porous sandstone, or, better, a slice of coke; saturate this with nitric acid. If a globule of mercury three or four millimetres in diameter be allowed to fall on the coke, the surface of the mass will be covered with minute beads of mercury. The nitric acid immediately attacks the under-surface of each sphere, producing an annular ring of nitrate of mercury. A short tube is thus formed, sustaining the metallic globule. As liquids rise in capillary tubes, but do not overflow the orifice, the periphery of the sphere is acted upon by the nitric acid, and lifted higher and higher by the deposited nitrate. The result is a tube of about twenty-five millimetres (one inch) in height, terminated by a minute sphere of mercury.

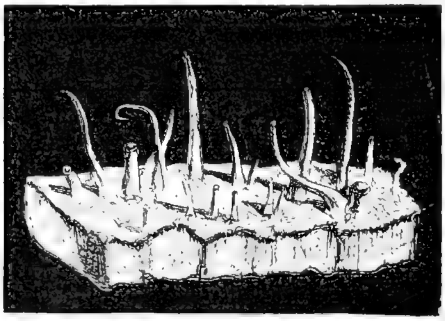
The cross-section of the stalactite is tubular; often, however, partially filled with interlacing crystalline planes. If nitrate of mercury is deposited more rapidly on one side, a twist is given, and a spiral tube is formed. Often a thin wall on one side predisposes the direction, and a curved stalactite is produced.

* Proc. Geo. Soc. 1865, 413.

It is well to consider briefly the stalactites that appear to have been formed mainly by deposition from water running over their surface. Of this class the siliceous stalactites well repay examination. Silica occurs in stalactite tubes of crystalline silicic anhydride, as in the specimens from Malwa, in Central India.

The chalcedonic form, however, is far more common, and the specimens from Trevascus Mine afford beautiful examples. The tubes are generally about two to three millimetres in diameter, and if a section through the length of the tube be made, the following structure will be easily made out by a hand lens or one inch objective. Firstly, we observe a slender opaque thread with a tube running down its entire length; over this opaque thread there is a covering of chalcedony. Frequently, but not invariably, the junction is marked by a vesicular structure.

To understand this it is necessary to turn to the artificial production of an aqueous solution of silica. By



NITRATE OF MERCURY STALACTITES

bringing together 112 grammes of silicate of soda, 67·2 grammes of dry hydrochloric acid, and 1 litre of water, and dialysing for four days, a solution containing 4·9 per cent. of silicic anhydride remains upon the dialyser; the chloride of sodium and excess of hydrochloric acid having diffused away. This solution becomes pectous somewhat rapidly, forming a solid jelly which dries in air into a glassy, lustrous hydrate. A solution containing 0·5 per cent. of silicic anhydride remains permanently limpid.

The minutest trace of a soluble carbonate, or a bubble of carbonic acid, causes a solution of silica to gelatinise rapidly. Professor Church has shown the importance of this fact in the formation of siliceous pseudomorphs of corals. By passing water containing 0·15 per cent. of silica, dissolved carbonic acid, and air, over the coral, he replaced the carbonate of lime by hydrated silica.

In the Trevascus stalactite under consideration, probably the opaque thread was originally carbonate of lime. The carbonate would have arrested and gelatinised the silica, the covering thus produced affording a colloid septum for the diffusing away of crystalloid salts.

This view is supported by the vesicular junction with the chalcedonic layer, as the escape of carbonic acid would probably have produced bubbles in the yielding jelly. Whether this be so or not, it is easy to convert stalactites of arragonite into siliceous pseudomorphs that present a close resemblance to the natural mineral.

W. CHANDLER ROBERTS

THE SHARPEY PHYSIOLOGICAL SCHOLARSHIP

WE are most pleased to report that the movement for the establishment of a "Sharpey Physiological Scholarship" at University College, in honour of Prof. Sharpey, is meeting with all the success that it deserves. Already, by the more or less private efforts of the secretaries and other members of the committee, a sum of £1,500 has been subscribed: much more, however, will be required in order to carry out the wishes of the promoters of the "Sharpey Memorial" scheme.

Having held his present professorship since 1836, Dr. Sharpey is well known to, and as thoroughly esteemed by, a very large number of old students, who have not only experienced the benefit of his clear, logical, and thorough method of teaching, but have felt the genial influence of his kindly sympathy, and the value of that breadth and soundness of judgment for which he is so remarkable. The large majority of his old and present students will now doubtless be delighted to take part in a movement destined to do honour to their favourite professor; and we believe that many of those who have been associated with Dr. Sharpey in his various official capacities in connection with science and education will also gladly avail themselves of this opportunity of testifying to their high appreciation of the valuable services which he has performed in both these capacities, and also of bearing witness to the strong feelings of personal regard with which he has inspired them.

The proposed memorial is of a nature likely to be peculiarly gratifying to Dr. Sharpey. The future "Sharpey Physiological Scholar" is destined to work in the Physiological Laboratory of the College, in the practical departments of the science; and successive students who may obtain this honourable distinction will, it is hoped, come for some time under the immediate supervision of Dr. Sharpey himself. The Professor has most liberally offered to present to the College his anatomical and physiological library, consisting of the best works of the older anatomists, a useful series of foreign scientific periodicals, and a large number of monographs by some of the most active and learned observers of modern times. It is proposed to place these books in a new class-room for practical physiology, which is about to be fitted up under the name of the "Sharpey Physiological Laboratory and Library;" and which, as part of the memorial, is to be adorned by a portrait of the man to whom the subscribers wish to do honour now, and whose memory they desire to perpetuate in the future. If the amount of the "Memorial Fund" is sufficient, it is also proposed that a bust of Dr. Sharpey should be executed for presentation to the College. The plan seems an excellent one, combining as it does the feature of being a thorough personal tribute of the most gratifying nature to Dr. Sharpey, destined to convey to successive generations of students a notion of the high estimation in which his services in the cause of science and education were regarded by his contemporaries, whilst it is also a movement likely to result in the further extension of that branch of science to which he has himself principally contributed. It is hoped that the study of practical physiology will thus be helped on more than it has hitherto been in this country, and that in time a school of practical physiology—the precursor of many others—may be established, equal to any of the now celebrated continental schools. It is expected that many of the fellows of the Royal Society and of other scientific bodies will gladly take this opportunity of doing honour to a man whom they all esteem so highly, and for whom so many entertain warm feelings of personal regard. We are glad to find that several of the foremost amongst them have already given evidences of substantial co-operation, and we trust that many others will follow their example.

THE ISTHMIAN WAY TO INDIA

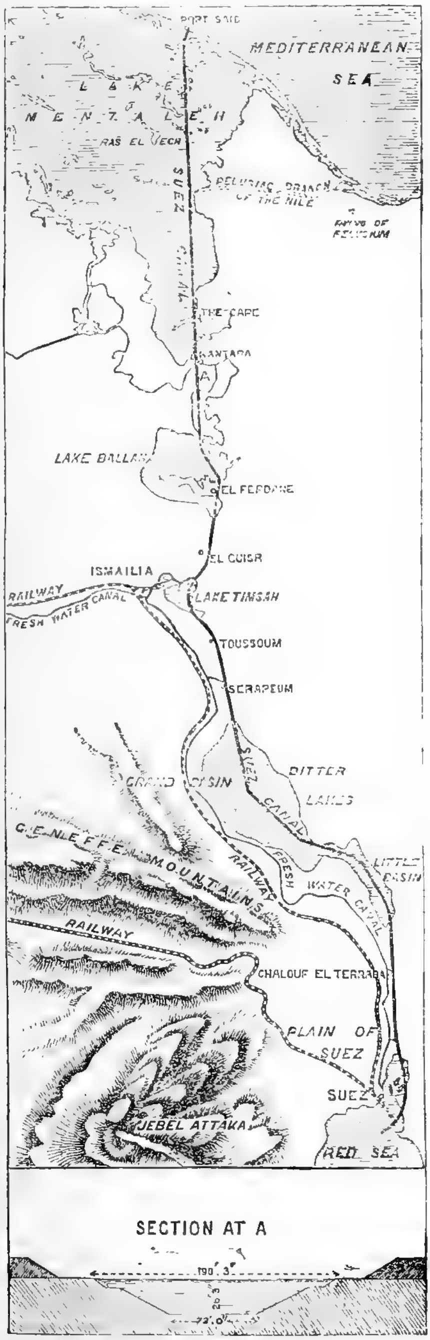
THE Canal has been opened. The flotilla, with its noble, royal, imperial, and scientific freight, has progressed along the new-made way from sea to sea. From Port Saïd, that new town between the sea and the wilderness, with its ten thousand inhabitants, and acres of workshops and building-yards, and busy steam-engines, the naval train floated through sandy wastes, across lakes of sludge and lakes of water filled from the Salt Sea; past levels where a few palm-trees adorn the scorched landscape; past hill-slopes on which the tamarisk waves its thready arms; past swamps where flocks of flamingoes, pelicans, and spoonbills, disturbed by the unwonted spectacle, sent up discordant cries; through deep excavations of hard sand or rock; across the low flat of the Suez lagoons, where Biblical topographers have searched for the track of the children of Israel; and so to the "red" waters of the great Gulf of Arabia. The flotilla has done its work: the Canal has been opened; and the distance by water to India is now 8,000 miles, instead of the 15,000 miles by the old route round the Cape of Good Hope.

It is a great achievement. So great, that we need not wonder that the capital of 8,000,000*l.* sterling with which it was commenced in 1859 was all expended, and as much more required, before the work was half accomplished. And perhaps we ought not to be too much overcome with pity for the 20,000 unlucky Egyptians—natives of the house of bondage—pressed every month up to the year 1863 by their paternal Government to labour, wherever required, along the line of excavations. How persistent are Oriental customs! Here we have in modern days—the days of power-looms, of steam printing-presses, and under-sea telegraphs—a touch of the old tyranny, the taskmasters and the groanings, associated in our memories with the very earliest of Egyptian history.

The length of the Canal is one hundred miles, and the depth, as the French engineers inform us, is to be everywhere twenty-eight feet, so as to admit of the passage of large vessels. It must not be supposed that an excavation of the depth above mentioned has been dug all across the Isthmus, for the level of the country is, for the most part, below that of the Mediterranean; consequently, miles of banks have been thrown up across the lowest tracts to form a channel for the water. In looking at a section of the whole route from Saïd to Suez—seventy-five miles in a direct line from sea to sea—the great extent of depression is well seen. In Lake Timsah it is about eighteen feet; in the Bitter Lakes, which stretch to a length of twenty-five miles, it is in places twenty-six feet. On the other hand, the elevations, though comparatively few, are somewhat formidable of aspect, particularly at El Guier and at Chalouf. The more this section is studied, the more forcible becomes the impression on the mind that a strait thickly studded with islands, as Behring's Strait, once separated Asia and Africa, and that by the drift from the Nile and the desert the sea has been filled up around the islands, with the exception of the lake depressions, until the present Isthmus was formed. Hence the difference of soil. The islands rising boldly up: El Guier, ten miles long, layers of sand and hard clay; Serapeum, three miles long, a kind of shelly limestone; and Chalouf, six miles long, composed of hard clay, sandstone rock, and conglomerate, the severest part of the excavation. Geologists have remarked upon the fact that the fossils found in the Chalouf ridge are identical with those of the London basin and the hill of Montmartre, whereby we learn that parts of Egypt, France, and England are of the same age.

The mountains of Abyssinia are every year diminished in size and height by the enormous periodical rains which wash down millions of cubic feet of mud and clay into the Nile. Vast clouds of sand are blown into the great river in its long course through the deserts; and these transported matters, caught by the strong current setting in from the Straits of Gibraltar, have been drifted to the eastward during immemorial ages, with consequences which are well known to those who have studied the geography and geology of the Isthmus. Such a transformation will be recognised as one of the ordinary operations of nature, when we remember that in 4,150 years the valley of the Nile has been raised eleven feet by deposits from the periodical floods, and that the land of Egypt is supposed to have been at one time a gulf stretching from the Mediterranean towards the Mountains of the Moon, but which became silted up by slow accumulations.

We may now form a clear notion of the region through



MAP AND SECTION OF THE SUEZ CANAL

which the Canal has been cut. A low, sandy shore is generally washed by a shallow sea. At Southend the pier extends for a mile and a quarter into the sea before meeting depth enough for an ordinary steamer; and the long piers at Lowestoft and other places on our eastern coast present themselves as illustrations in point. So shallow is the sea off Port Saïd, that the mouth of the harbour had to be commenced two miles from the shore, for there only did the required depth of twenty-six feet of water begin. Less than this will keep out vessels of the largest class. The western pier, the one against which the whole weight of the powerful current falls, projects more than two miles into the sea; the one to the east is half a mile shorter. These breakwaters have been built up of concrete blocks weighing twenty tons each, made on the spot from the sand dredged out of the harbour mixed with hydraulic lime brought from Marseilles. Spaces were left between the blocks to be filled up by the seadrift; but though there have been great deposits of sand and mud outside the breakwater, the filling up of the gaps has not been so speedy as was anticipated, and heaps of sand which drifted through have had to be dredged out again. Of course, while money for payment is forthcoming, any number of dredging-machines may be employed; but can that process be depended on when enthusiasm shall have evaporated, and there is nothing but the prosaic work of letting ships in or out to animate the promoters? Will it always be possible to prevent the formation of such soft banks as that on which the "Prince Consort" and the "Royal Oak" grounded on their arrival to take part in the opening of the Canal?

There is something instructive in the operations which have so diligently been carried on at the mouth of the Tyne, where a passage through the bar is essential. To maintain this passage, eighteen feet deep only, more than four million tons of sand must be dredged out every year. This has been going on for ten years or more, and the channel is not yet secure.

Not only the harbour of Port Saïd, but the greater part of the Canal itself, has been formed by dredging; and this, in soft ground or through the sludge of Lake Menzaleh, was comparatively easy work. The mud raised from the bottom was spread along each margin of the newly-scooped-out channel; but it would not stay there, and for a time the prospect of maintaining an open channel seemed as hopeless as George Stephenson's first attempt to carry the Liverpool and Manchester railway across Chat Moss. No sooner was the Menzaleh mud deposited in its new position, than it either slipped back into its former bed, or squeezed the soft soil on which it lay into the channel. The dredgers were in despair over a task in which no progress could be made, until one day one of the labourers showed that if, instead of great heaps, a thin layer of the mud were spread and left to harden in the sun, it would not slip back. So layer by layer the mud was spread, the banks were built up, and a way for the Canal was opened through such slime as was used in ancient days for the making of bricks.

In the hard ground the "bondagers" dug with pick and spade, and carried away the loosened soil in baskets. But when they were supplemented by European labourers, powerful excavating machinery was employed, and the line of works presented as busy a spectacle as an English railway in course of construction, or the main drainage works in their progress towards Barking Creek across the Essex marshes. The slopes of the cuttings were alive with labourers and machines, by which the excavated earth was lifted and run off to a distance. The power of the digging-machines may be judged of from the fact that some of them could dig out 80,000 cubic metres of soil every month, and that on one occasion the quantity was 120,000. A dozen or two of machines working at this rate would soon make a big gap through the high grounds before them.

The lakes of water on the Isthmus may be regarded as Nature's contribution towards the success of the Canal; for in them the only labour required is to dredge a channel which will give a depth of twenty-eight feet. Moreover, they may be used as ports. This is especially the case with Lake Timsah, on the shore of which stands the newly-built town of Ismaïlia, the half-way stopping place for travellers on the Canal. Here anchored the flotilla during the progress of the opening, and the dark-skinned children of the Prophet were seen mingled with throngs of fair-complexioned Giaours in friendly rejoicings.

Ismaïlia is an important place, for it is the pumping-station of the fresh-water canal which was first made in order to supply the thousands of labourers with drink, and water for their works. On this pumping-station all the country between Lake Timsah and Port Saïd depends for its supplies of the precious element.

The hollow of the Bitter Lakes, six miles wide in the widest part, is believed to have been at one time connected with the Red Sea. The level of the water in these lakes has been brought up to that of the sea by a re-opening of the connection. In March of the present year, all preparations being complete, the water was admitted, and a great stream, pouring in from the Mediterranean and from the Red Sea, gradually rose upon the arid saline slopes of the deep and desolate basin. For some weeks the flow went on, until, as was estimated, two thousand million cubic metres of water had flowed in, and the level was established. The area of the lakes will be largely increased by this contribution from the two seas; and it will be interesting to watch whether in connection with the two canals—the salt-water and fresh-water—any modification of the climate of the Isthmus may be produced. Much has been said, too, about the loss that will take place by evaporation under the sun of Egypt: the amount is so great as to be almost incredible. This loss will have to be provided for; as also the effect of blowing sands, which will accelerate the tendency of the bottom to grow towards the surface, always observable in canals.

Up to the last moment predictions from various quarters have been heard that no big ships would ever effect the passage of the canal. But while we write these lines, telegrams from the East inform us that *L'Aigle*, the French yacht, with her Majesty the Empress on board, had got through, and was anchored in the Red Sea. From the same source we learn that the Peninsular and Oriental steamer *Delta*, drawing 15½ feet of water, had arrived at Ismaïlia from Port Saïd, but had touched ground a few times on the way. The Egyptian vessel *Lattif* attempted the passage, but for want of sufficient depth had to return; difficulties occurred with other vessels, and the banks of the Canal were much damaged.

But the Khédive has invested M. de Lesseps with the Grand Cross of the Order of the Osmanli, and the Emperor Napoleon has appointed him to the rank of Grand Cross of the Legion of Honour. We may therefore hope for the best in all that appertains to the Suez Canal, and that foreigners will believe that Englishmen are too ready to admire good work to feel jealous of the energetic hearts by whom it has been accomplished.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents.*]

The Meteor of November 6th

METEORS being in season just now, all facts respecting them will, I presume, be acceptable. The public have lately been treated to a great number of letters in newspapers descriptive of the remarkable meteor of Saturday, November 6th—perhaps I should rather say *a* instead of *the* remarkable meteor, because, from the discrepancies as to the time of the appearance and the differences in the description, I am inclined to believe that more than one meteor of unusual splendour was seen on that evening. I need hardly say how important it is to have observations of the visual direction of these bodies as viewed from stations widely separated from each other, because it is only observations of this kind which can afford data for judging of the distance of a meteor. In the hope of contributing information which may assist in clearing up this interesting question, I venture to add another letter to the many which have already appeared.

At five minutes before seven on Saturday evening, November 6th, while walking with my back towards the south, near the village of Rothbury in Northumberland, I was startled by a brilliant light behind me, and on turning I saw a magnificent meteor descending from the eastward at an angle of about 45° to the southern horizon. Its colour was a bluish-white, and it left a train which looked exactly like that of a large rocket, but which did not remain visible to my view for more than about fifteen seconds. The meteor did not appear to me to burst, although pieces seemed to separate from it before it expired. At the moment of extinction it was about 12° or 14° above the horizon, and its direction was then S.S.W. I am quite sure as to the time of the occurrence to within a minute, because, although I could not see to read my watch at the moment—a chronometer on which I can depend, and which I know was right—I hastened to the nearest light, about four hundred yards distant, where I ascertained that the time was one minute to seven, which, allowing about four minutes for walking the four hundred yards, would make the time of the appearance five minutes to seven. So far as I have seen, there is but one describer of this meteor whose record of the time exactly agrees with mine, and as it is incredible that two such unusual meteors should occur in the same minute, it is almost absolutely certain that he and I saw the same. My co-observer was the writer of a letter in the *Times*, signed J. A. Cayley, dated from the neighbourhood of Bristol, where he witnessed the phenomenon at a distance of two hundred and sixty miles from where I saw it in Northumberland. As viewed by him, it appeared to descend from the zenith to about 20° above the *western* horizon, while I, as already stated, saw it in the *south*. His description of the meteor differs from mine only in regard to the train, which is described as continuing visible to him for fifteen minutes, a difference which may be attributed to its being nearer and more overhead to him than to me.

I will not hazard even an approximate calculation of distance from the data I have given, but I confess my inability to reconcile the different angles under which this object was seen at opposite ends of a base-line having Bristol at one end and Rothbury at the other, with the supposition that its height did not exceed that which is ordinarily assigned to the atmosphere. At all events, if the atmosphere exists at the height of this meteor, it will be more attenuated than in the exhausted receiver of the most perfect air-pump, and it is difficult to conceive how air so rarefied can so oppose the flight of a solid body as to produce the intense ignition exhibited in a meteor. Yet it seems impossible to attribute the incandescence of these bodies to any other cause than the resistance opposed by the atmosphere to their prodigious velocity.

W. G. ARMSTRONG

Newcastle-on-Tyne, Nov. 22, 1869

Lectures to Ladies

No one can appreciate more heartily than I do the excellent article on "Lectures to Ladies" which appeared in NATURE No. II.; but I feel far from sanguine of success attending the efforts there referred to. If we put aside the impulse of dilettantism and the spirit of rivalry as against men, there will, let us hope, be left a very fair residue in the shape of love of learning, for learning's sake, as a reason for attendance; and it is only this pure love of learning which can make such lectures in the long run successful. It cannot, however, be such a love which brings to the lectures of the University College Professors, Lady Barbara, who sneers aloud when the lecturer wisely lays a sure foundation of elementary facts and ideas; or which carries to South Kensington the Hon. Miss Henrietta, who tosses her head when she finds the great Mr. Huxley paddling about in that common river the Thames, and treating his audience as if they were little girls at the Finsbury Institution.

I very much fear that the Lady Barbaras of the present generation are beyond redemption, and that many earnest men are wasting their strength in trying to win the minds of intellectual coquettes.

There is an order of women, however, having in their number, as I know full well, some of the brightest and best of the women of England, to whom such lectures would be as manna in the wilderness. To women struggling, as many of us are, to get their daily bread by the hard task of teaching, and in the struggle getting glimpses of the sweetness and the light of real knowledge, the chance of listening to real teachers would be an inestimable boon. These are the women to whom, it must be remembered, the early training of many children is entrusted; and if our children are to be properly trained, the teachers must first of all be faithfully taught.

Nearly all these women are practically shut out from the lectures both at South Kensington and University College, because none of the lectures are given in the evening.

At University College they don't pretend to care for such an audience. At South Kensington something is said about those engaged in teaching: a mere mockery; for how can any one who is hard at work all day go to a lecture in the forenoon? I trust, Sir, you will use your already powerful voice in urging, especially on our scientific teachers, the—to me it seems—great duty before them to help those who need and cry for help the most.

M.

NOTES

The three annual medals of the Royal Society have been awarded thus: The Copley Medal goes to M. Regnault, one of the first among the many living French physicists and chemists: one of the Royal Medals has been conferred on Dr. Matthiessen, distinguished for his chemical and physical researches; while Sir Thomas Maclear, the Cape astronomer, with whose valuable contributions to science all are doubtless familiar, carries off the other. The medals will be presented on the 30th instant, at the annual meeting of the Society.

We hear that Dr. Balfour Stewart, F.R.S., so well known for his many scientific researches, has resigned the appointment which he held under the Meteorological Committee. As the arrangements between the Meteorological and the Kew Committees are not well understood, we may mention that the exact appointment resigned is that of Secretary to the Committee, and Director of their Central Observatory.

All anxiety regarding the fate of Dr. Livingstone is, we are rejoiced to say, at an end. From a recent telegram we learn that in May last he was at Ujiji, on the east coast of Lake Tanganyika, in lat. 5° S. To this place his supplies had been sent. Burton gives the distance from the coast as 540 geographical miles, increased by the winding route pursued to 950 miles, occupying 150 days' march. It is the great mart for slaves and ivory and palm oil, and the most fertile place in that portion of Africa. The fair season lasts from May to September. While on this subject we would mention that the map which appeared in our last issue was drawn by the author of the paper, and did not emanate officially, as our expression might seem to indicate, from the Royal Geographical Society.

The following is an extract from a letter addressed by Mr. Lyon Playfair, M.P., to the honorary secretary of the City of London Middle-class School:—"As part of your freehold I observed some inferior houses the site of which would be admirable for chemical laboratories and scientific museums in relation to commerce. I should like to see built upon this site a building suited for these purposes, open to the school during the day, and to the working classes in the evening. No boy with such advantages need leave the upper classes of the school without being able to examine the various kinds of merchandise which he will meet with in his occupations, so far, at least, as would enable him to test chemically their relative excellences, or detect their adulterations. No boy need then leave the school without having had his physical and political geography copiously illustrated by objects of natural history, in their relation to the imports and exports, upon which the prosperity of the country so largely depends. The cost and maintenance of such a building as that indicated may be estimated at a sum of from 12,000*l.* to 15,000*l.* But what would this sum be to the great London corporations, which, by their recent public meeting, have shown their anxiety to co-operate in the advancement of technical education? Abroad we see much larger sums spent in the erection of mere chemical laboratories to advance the industrial education of the people. Berlin and Bonn have recently erected them at the expense of 50,000*l.* each, and Leipsic, I understand, at a cost of about 30,000*l.* The much smaller sum that I have indicated as sufficient for your wants might be subscribed in a single day by such wealthy corporations as the Goldsmiths', Grocers', Mercers', Haberdashers', Fishmongers', Drapers', Skinners', Merchant Taylors', Clothworkers', and Salters' Companies, and others with which you must be more familiar than myself. They have expressed themselves zealous and willing, and I am sure could not engage in a more profitable expenditure." Here is a fair challenge, which we hope will be fairly met. The benefit which would result from adopting Mr. Playfair's suggestion is simply incalculable.

At the Meeting of the French Academy of Sciences on the 15th inst., M. des Cloiseaux was elected a member of the Section of Mineralogy and Geology, in the place of the Vicomte d'Archiac.

The volume of the Memoirs of the Royal Astronomical Society about to be issued will consist of Lieut.-Col. Tennant's Report on the Total Eclipse of the Sun of August 17-18, 1868. It will be copiously illustrated with engravings of the various phases of the Eclipse. The volume owes much to the scrupulous care with which Mr. Warren de la Rue, in the author's absence, has superintended its printing and the enlargement of the photographs.

The American Government evince a great liberality in the encouragement they afford to scientific publications. It was thus that Dr. George Engelmann was enabled to produce the 72 exquisite plates which illustrate his paper on "The Cactaceæ of the Mexican Boundary Survey," a district which contains at least one-tenth of all the known species of cactus. There is another recent instance. Until 1867, the physical geography of the Californian peninsula may be said to have been unknown. In that year Mr. J. Ross Browne, Mr. W. M. Gabb, of the Geological Survey, and Dr. Von Lohr, of the School of Mines, Freiburg, made a scientific *reconnaissance*, with a corps of assistants, throughout the whole length of the peninsula. The account of their researches forms a valuable contribution to geographical knowledge, and will be found in Mr. Ross Browne's "Official Report on the Mineral Resources of the United States for 1868." The first correct map of the district, almost the whole of which was purchased cheap from Juarez by an American venture, the Californian Land Company, at a time when it was probable that Maximilian would be successful, was compiled from the labours of this party.

The first meeting of the Oxford Ashmolean Society for the present Term will be held on Monday next, when a communication will be made to the society by Professor Lawson, "On the Nature of Chlorophyll, and the changes it undergoes." Mr. Heathcote Wyndham will explain also a modification of Galton's Altazimuth for Geological Surveying. Certain specimens recently added to the University collections will be exhibited at the meeting.

We extract the following from the letter of a correspondent in Algeria:—"I was on the point of starting for Grand Kabylie, with the view of searching for ferns, &c., when one of those horrid tempests came on for which the N.W. point of the compass here is celebrated. It did great damage, and its effects at Oran were most disastrous. The magnificent new harbour recently finished there has been swept away as completely as a child's castle of cards, and, like the Temple of Jerusalem, not one stone stands on another. Great efforts were made to preserve it; the General Commanding the Provinces went down and sat before the waves in a chair, like Canute, with all the material of the engineer department, in the way of chains and tackle, around him. *Sa Grandeur* the Bishop came next, with bell, book, and candle, and blessed the sea; next came the Mahomedan Mufti with his Koran; but the waves laughed at them all, and toppled over the immense masses of concrete of which the breakwater was formed, like ninepins."

We have received the following from our Dublin Correspondent:—The newly-appointed Professor of Geology at Trinity College, Dublin—Dr. Macalister—commenced a course of lectures on the Invertebrates last week. Referring in his introductory lecture to the researches of Pouchet, Pasteur, Massalongo, and others, on spontaneous generation, he seemed to regard the proofs of its existence as now fully established. The examination for the Natural and Experimental Moderatorship has just been concluded: the gold medals were awarded to Lloyd, West, and Wilson, and the silver medals to Colles, Tweedy, Hart, Rainsford, Abridge, and MacIvor. The subjects selected by the first gold medallist were chemistry, botany, zoology, and palæontology. The librarianship vacant by the death of the Rev. Dr. Todd has not yet been filled. The candidates are the Rev. Dr. Dickson, F.T.C.D., and the Rev. Dr. Reeves. The former is perhaps the more popular candidate, as, in spite of the high position held by Dr. Reeves as an archæologist, it is felt desirable that the librarian of so important a library should take as great if not a greater interest in modern than in ancient books. The University of Dublin has established Examinations for Women. Two examinations will be held annually, one for senior, the other for junior candidates. The examination for junior candidates will be open to all who are above 15 and under 18 years of age; the examination for senior candidates to all who are above 18 years of age. A committee, nominated by the board of Trinity College, will appoint examiners, determine the times, places, and subjects of examination, and make an annual report to the board. The senior lecturer of Trinity College will exercise a general supervision over the conduct of all the examinations. Examinations will be held at any place where a ladies' superintending committee shall be constituted, and at least twenty candidates guaranteed to present themselves. An examiner will be sent to each place, who, in conjunction with the Ladies' Committee, will arrange the details of the examination. Every candidate presenting herself for examination will be required to pay a fee of twenty shillings, together with the local fee, the amount of which is to be determined by the local committee. No class lists will be published; but, after each examination, notice of the result will be sent to the home of each candidate. Special excellence in any subject will be notified on the certificate. For a certificate of honour, superior answering in the compulsory and two optional subjects will be required. The first examination will be held at some time between the 25th of March and the 15th of April, 1870. Further information can be obtained by application to the senior lecturer, Trinity College, or to the secretaries of the ladies' local committees. No head of any educational establishment is to be a member of a Ladies' Committee.

The Academy of Natural Sciences at Philadelphia have sent out the third part of Vol. VI. of their "Journal," a handsome imperial quarto which affords dimensions for ample illustrations. The part contains two papers—on the Distribution of Freshwater Fishes in the Alleghany Region of South Western Virginia, by Mr. E. D. Cope; and on shells, Unionidæ, Melindæ, &c., by the veteran Isaac Lea. The plates, numerous and well-executed, particularly the coloured representations of the fishes, exemplify at once the interest taken by the Academy in Natural History, and the painstaking of American artists. This large book is accompanied by the volume of "Proceedings" for 1868, in which we find papers and notices on more than fifty different subjects; and we gather from the annual report at the end of the volume, that the citizens of Philadelphia as well as the naturalists appreciate natural history, for during the year they visited the Academy's Museum to the number of 65,769 persons, and they have contributed 100,000 dollars towards the cost of a new building for the accommodation of the Academy and their collections. The library contains nearly 22,000 volumes, and, in common with the natural history collections, is continually increased by donations. Among those recently acquired were the large collections made by the Orton expedition to Equador and the Upper Amazon. We may fitly close this paragraph with a notice published by the Academy, that "the children of the late Augustus E. Jessup, wishing to carry out the intention of their father, pay to the Academy the sum of 480 dollars per annum, to be used for the support of one or more deserving poor young man or men, who may desire to devote the whole of his or their time and energies to the study of any of the Natural Sciences."

M. Elie de Beaumont has been elected vice-president of the Collége Français for the year 1869–70. M. Bastien has been appointed assistant naturalist to the chair of Pharmacy in the same institution in place of M. Pouchet.

The chair of Geology and Mineralogy of the Faculty of Sciences at Lyons is vacant; also that of Chemical Toxicology at the École Supérieure of Paris.

Our American friends intend holding an International Exhibition at New York in 1871.

Another edition of Hirt's Atlas of the three kingdoms of nature has been issued in commemoration of the Humboldt centenary.

Baron Claus von der Decken's Travels in East Africa has reached the third volume. The entire work, most exhaustive as it is in every particular, is expected to be complete in a year.

We are promised shortly "the Scientific Results of a Journey in Brazil," which contain Professor L. Agassiz's observations on the natural history, and an account of Mr. F. Hart's examinations of the physical geography and geology, of the region traversed by the well-known recent exploring expedition.

A geographical congress is to be held at Anvers, in August, 1870.

We believe that Mr. Charles Hamilton, well-known as the author of a work on Hunting in Southern Africa, and by his travels in Brazil, is about to undertake a scientific exploration of the Red River, and some of the Hudson Bay settlements, with a view to promote our knowledge of the zoology of the district.

We have received from Mr. Browning four stereograms of the planet Mars; a chart of Mars on Mercator's projection; and descriptive remarks on the stereograms by Mr. Proctor—and very interesting they all are. We are glad that Mr. Proctor, who seems determined to become the chartographer of astronomy, has taken Mars under his wing, and with Mr. Browning's aid, has brought a discussion of all the observations of modern astronomers—the lamented Dawes being first and foremost among them—to such a beautiful and practical ending.

The third fasciculus of the second volume of the "Archives du Musée Teyler" has just been published at Haarlem, in the same handsome style as the former parts. It contains papers, all by Dr. Van der Willigen, on subjects of much importance at present in optical and chemical science, as may be seen in the following list:—Sur la réfraction du quartz et du spath d'Islande; Sur la réfraction et la dispersion du flint-glass et du crown-glass; Les indices de réfraction des mélanges d'alcool et d'eau, et des mélanges de glycérine et d'eau; Les indices de réfraction de la benzine; Les indices de réfraction des dissolutions des chlorures de calcium, de sodium, d'ammonium, et de zinc, &c. Many of the results are given in a tabulated form which facilitates reference.

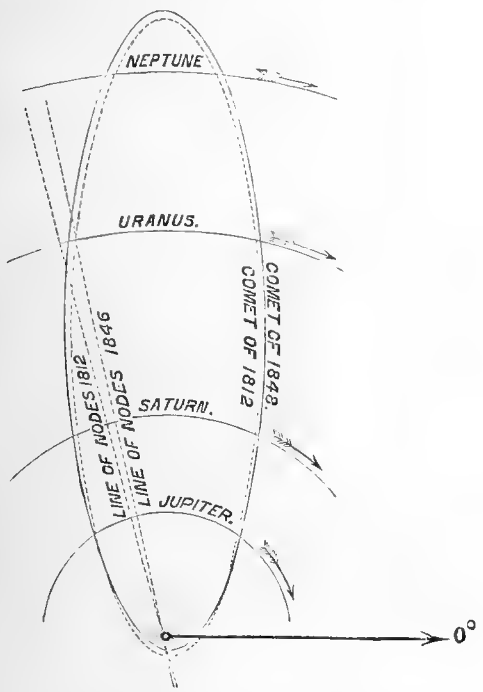
We understand that Mr. B. Loewy, well known from his connection with the Kew sun-observations, is engaged in publishing a collection of problems in physical science, with their solutions, which will embrace all branches generally required for the various public examinations of our Universities.

ASTRONOMY

Kirkwood on the Origin of Comets

THE recent important investigations of Hoek on the origin of comets may be said to have opened out quite a new field of astronomical research of the highest importance. We are glad, therefore, to lay before our readers an abstract of a continuation of the work which we owe to Professor Kirkwood, who has communicated it to *Sillimans' Journal.* Professor Kirkwood has dealt with the comets 1812, i. and 1846, iv.

The wonderful similarity of the elements of these, except in the longitude of the ascending node, is very remarkable. It is also noticeable that the longitude of the *descending* node of the latter is very nearly coincident with that of the *ascending* node of the former. These remarkable coincidences are presented to the eye in the following diagram, where the dotted ellipse represents the orbit of the comet of 1812, and the continuous curve, that of the comet of 1846.



Dr. Kirkwood remarks :—

"It is infinitely improbable that these coincidences should be accidental : they point, undoubtedly, to a common origin of the two bodies." And adds :—

"The theory of comets now generally accepted is that they enter the solar system *ab extra*, move in parabolas or hyperbolas around the sun, and, if undisturbed by the planets, pass off beyond the limits of our system to be seen no more. If in their motion, however, they approach very near any of the larger planets, their direction is changed by planetary perturbations; their orbits being sometimes transformed into ellipses. The new orbits of such bodies would pass very nearly through the points at which their greatest perturbation occurred : and accordingly we find that the aphelia of a large proportion of the periodic comets are near the orbits of the major planets. 'I admit,' says M. Hoek, 'that the orbits of comets are by nature parabolas or hyperbolas, and that in the cases when elliptical orbits are met with, these are occasioned by planetary attractions, or derive their character from the uncertainty of our observations. To allow the contrary would be to admit some comets as permanent members of our planetary system, to which they ought to have belonged since its origin, and so to assert the simultaneous birth of that system and of these comets. As for me, I attribute to these a primitive wandering character. Travelling through space they move from one star to another in order to leave it again, provided they do not meet any obstacle that may force them to remain in its vicinity. Such an obstacle was *Jupiter*, in the neighbourhood of our sun, for the comets of Lexell and Brorsen, and probably for the greater part of periodical comets; the other part of which may be indebted for their elliptical orbits to the attractions of *Saturn* and the remaining planets.

"'Generally, then, comets come to us from some star or other. The attraction of our sun modifies their orbit, as had been done already by each star through whose sphere of attraction they had passed. We can put the question if they come as single bodies or united in systems. This is the point I have undertaken to investigate. Since some time already I had felt the truth of the following thesis :—

"'*There are systems of comets in space that are broken up by the attraction of our sun, and whose members attain, as isolated bodies, the vicinity of the Earth during a course of several years.*'

"In the researches here referred to it has been shown by M. Hoek that the comets of 1860 iii., 1863 i., and 1863 vi., formed a group in space previous to their entrance into our system. The same fact has also been demonstrated in regard to other comets which need not here be specified. Now, the comets of 1812 and 1846, iv. have their aphelions very near the orbit of Neptune, and hence the original parabolas in which they moved were probably transformed into ellipses by the perturbations of that planet. Before entering the solar domain they were doubtless members of a cometary system. Passing Neptune near the same time, and at some distance from each other, their different relative positions with regard to the disturbing body may account for the slight differences in the elements of their orbits.

"*At what epoch did they enter the solar system?* The mean between the longitudes of the aphelia of the two comets is 271° 41′. Neptune had this longitude in 1775; the comet of 1812, in 1777; and that of 1846, in 1809. Now, with the known period of Neptune and the periods of the comets as determined by Encke and Peirce, we find (neglecting perturbations) that—

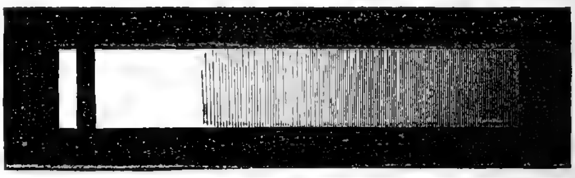
Neptune was in longitude 271° 41′ in the year 694 B.C.
The Comet of 1812 ,, ,, ,, 696 ,,
,, 1846, iv. ,, ,, ,, 696 ,,

It seems, therefore, that the three bodies were very nearly together about 695 years before the Christian era. It is consequently not improbable that the elliptical form of the two cometary orbits dates from this epoch."

BOTANY

Spectroscopic Examination of Diatoms

THE vegetable nature of the Diatomaceæ is now generally admitted, but if any further proof were needed we have it in marked results from the application of the spectroscope. Mr. H. L. Smith has been enabled to prove the absolute identity of *chlorophyll*, or the green endochrome of plants, with *diatomin*, or the olive yellow endochrome of the Diatomaceæ. The spectrum-microscope used was made by Browning, of London. Mr. Smith states that it is not at all difficult to obtain a characteristic spectrum from a living diatom, and to compare it directly with that of a desmid, or other plant. From about fifty comparisons of spectra, he concludes that the spectrum of chlorophyll is identical with that of diatomin. The spectrum in question is a characteristic one, and is figured below.



A very black, narrowish band in the extreme red, reading at the lower edge, which appears to be constant, about $\frac{7}{8}$ of Mr. Sorby's scale, is too characteristic to be mistaken. There are two other very faint bands, not easily seen, and somewhat more variable in position. The black band in the red is always present, and is remarkably constant in the position of its lower edge. In making comparisons of spectra it is of the utmost importance that the slit of the spectroscope should be absolutely in the focus of the achromatic eye lens. If this be not attended to there will be a slight parallax; and bands really identical in position, e.g., those of blood (scarlet cruorine), will not absolutely correspond when two spectra are formed, one from blood on the stage of the microscope, and the other from the same on the stage of the eyepiece.

The dark band of the chlorophyll spectrum is slightly variable in width—and the action of acids and alkalies sometimes causes a slight displacement, the former raising (moving toward the blue end) and the latter depressing. The endochrome of a diatom after treatment with acid is green, and the acid, in this case, produces scarcely any displacement of the band, which may be observed even in the dark reddish mass of the dead Diatomaceæ, almost identical in colour with the ferrous carbonate so often found in bogs where the larger diatoms are abundant; and what is more remarkable is, that the carbonate gives no absorption bands at all. As a general rule, alcoholic solutions of chlorophyll and diatomin have the band slightly depressed, reading 1 to $1\frac{1}{2}$ on the interference scale.—[Amer. Jour. Sci. and Arts.]

CHEMISTRY

Thallium Salts.—I.

MM. LAMY AND DES CLOISEAUX have resumed the study of the principal thallium salts, with the view of ascertaining their chemical composition, optical properties, and crystalline form (Annales de Chimie et de Physique, xvii. 310). The method of obtaining crystals was that which M. Deville has for a considerable time been in the habit of employing in his laboratory. A given substance is placed in contact with water, or some other solvent, either in a closed or lightly covered vessel, and exposed to the usual conditions of temperature of an inhabited apartment; if these do not suffice, the liquid is heated every day for an hour to a certain extent. In course of time, even the most microscopic crystals, if submitted to this process, become large, well-formed, and transparent.

The thallium in these salts was determined as iodide; a compound which from its sparing solubility (especially in water containing a little potassic iodide), as well as on account of its great specific gravity and crystalline character, is very well adapted to the purpose. The density of thallous *sulphate*, $Tl2SO_4$, is 6·603,* and its form a right rhomboidal prism, geometrically and optically isomorphous with ammonic sulphate. The crystals often appear unsymmetrical, on account of the unequal development of the different faces. The optic axes are wide apart; and the dispersion of the axes, as observed in oil, is feeble, with $\rho < \nu$. To the already known thallium *alums* may be added a mixed series, having the general formula:

$$(Al_2O_3 . Fe_2O_3)3SO_3 + (K_2O . Tl_2O)SO_3 + 24Aq.$$

Special attention is directed to one of these, which was obtained accidentally in the course of a lixiviation, and had the formula:

$$[(Al_2O_3)^{\frac{2}{3}}(Fe_2O_3)^{\frac{1}{3}}]3SO_3 + [(K_2O)^{\frac{3}{4}}(Tl_2O)^{\frac{1}{4}}]SO_3 + 24Aq.$$

Its colour is slightly yellow, and in solubility it much resembles potassic alum. After several solutions and recrystallisations, the whole of the iron is removed, and the following alum appears:

$$Al_2O_3 . 3SO_3 + [(K_2O)^{\frac{3}{4}}(TlO)^{\frac{1}{4}}]SO_3 + 24Aq.$$

Zinco-thallous sulphate—

$$Tl_2SO_4 + ZnSO_4 + 6H_2O,$$

which had already been described by Willm and Werther, belongs to the oblique rhomboidal prismatic system, and is geometrically isomorphous with ammonio-ferrous sulphate, potassic magnesio-sulphate &c. (as, indeed, Werther has shown); but it is optically different from these salts, both in orientation and in the sign of its acute bisectrix (negative).

Plane angle of the base	107° 5′ 14″
Plane angle of the lateral faces	99° 31′ 24″
Obliquity of the primitive prisms . .	106° 10′ 00″

The optic axes lie in the plane of symmetry. There is a strong proper dispersion with $\rho < \nu$. The *inclined* dispersion is weak, and only brought out by a difference in the brightness of the colours lying at the edges of the hyperbolæ of the two systems of rings. Thallous *nitrate*, $TlNO_3$, has the specific gravity 5·550, and occurs in right rhomboidal prisms of 125° 52′ (the corresponding angle for nitre is 118° 50′). The plane of the optic axes is perpendicular to the corresponding plane in potassic nitrate. The acute bisectrix is negative, and the dispersion of the axes considerable, with $\rho < \nu$. This salt had been already examined optically by Miller. In order to prepare thallous *carbonate*, (Tl_2CO_3), a saturated solution of thallous oxide in alcohol was exposed to air, in contact with a lamina of thallium. At the end of six months, very large crystals were obtained. These have an adamantine lustre, and a specific gravity 7·164; they belong to the clino-rhombic system, thus agreeing neither with plumbic, potassic, nor ammonic carbonate. Macles by hemitropy round one particular axis, are frequently observed. The plane of the optic axes is normal to the plane of symmetry, and almost exactly perpendicular to the base. The acute bisectrix is negative, and normal to the horizontal diagonal of the base; the double refraction energetic. The dispersion of the optic axes is well marked, with $\rho < \nu$; while the *horizontal* dispersion is, on the contrary, inappreciable. An attempt to prepare other thallous carbonates did not succeed.

Di-thallous *phosphate*—

$$2[Tl_2HPO_4] . H_2O,$$

is a very soluble salt, anhydrous at 200°, and crystallises in the rhombic system. Lustre vitreous. The dispersion of the optic axes is strong, with $\rho > \nu$. *Mono*-thallous *phosphate*—

$$TlH_2PO_4,$$

is very soluble in water, and readily crystallises in long voluminous needles which were submitted to the growing process already described. Density 4·723. The crystals may be referred to a clino-rhombic prism of 34° 59′, having a base only slightly sloping towards the lateral faces. Macles by hemitropy are common, giving rise to a re-entering angle of 176° 32′. The plane of the optic axes is parallel to the horizontal diagonal of the base. Acute bisectrix negative; horizontal dispersion indistinct; proper axial dispersion considerable. The *pyrophosphate*— $Tl_4P_2O_7$, crystallises in magnificent transparent prisms, soluble in water with partial decomposition, softened by a heat of 120°, and having the density 6·786. Its form is an oblique rhomboidal prism. The crystals are fragile, and have a somewhat adamantine lustre. The plane of the optic axes is normal to that of symmetry, and almost parallel to the base. While the horizontal dispersion is but slight, the proper dispersion of the axes is the greatest hitherto observed, as shown by the following means of measurements taken in oil and air, determining the apparent separation of the axes in air at 24°:

$$2E = 125° 48′ \text{ (red rays)}; 112° 30′ \text{ (yellow)};$$
$$2E = 89° 47′ \text{ (green rays)}; 52° 34′ \text{ (blue)}.$$

The *hydrous pyrophosphate*—

$$Tl_4P_2O_7 + 2H_2O,$$

separates from the mother-liquid of its predecessor. It is soluble in water with but little decomposition; but it is less stable at a high temperature than the anhydrous salt, which, on the other hand, it exceeds in the intensity of its vitreous lustre, its hardness and cohesion. The plane of the optic axes is normal to the plane of symmetry: the acute bisectrix negative and perpendicular to the horizontal diagonal of the base. Horizontal dispersion feeble; proper dispersion of the axes considerable, with $\rho < \nu$. The *ammoniacal thallous phosphate*—

$$3NH_3 . H_3PO_4 + 2NH_3 . H_2TlPO_4$$

is obtained by adding ammonia to the common phosphate, filtering to remove tri-thallous phosphate, and evaporating the mother-liquid. The crystals are very soluble in water, and completely isomorphous with ammonic phosphate. Their figure is that of a right prism with square base, elongated in the direction of the vertical axis, and terminated by an octohedron of 119° 50′. The double refraction is on a negative axis.

E. J. M.

* The temperature in this and following determinations is not given in the memoir.

PHYSICS

Pfaundler on the Regelation of Ice

THE fact observed by Faraday that two pieces of ice freeze together when brought into contact has met with various explanations. Helmholtz, for example, assumes that pressure is always at work in regelation; hence depression of the fusion point of the ice, and a cold sufficient to freeze a small portion of water in another part of the mass. Tyndall, on the other hand, admits the hypothesis of pressure only where it is actually observable; but, in other cases, explains the phenomena by a difference between the fusion-point inside and at the surface of the ice. Schultz has actually verified Tyndall's theory with water from which the air had been expelled.

Pfaundler has recently reconsidered this subject, and states the question as follows :—" Can a piece of ice, surrounded by water at 0°, preserve its shape if the water undergo no disturbance?" So far as we know at present, both weight and figure remain unchanged. Either, then, a part of the ice must melt, or a part of the water freeze, or both of these phenomena happen together. Such alterations involve certain mutations of the amount of heat contained in the surrounding water, or, at least, of the equilibrium of temperature in different parts of the liquid. Now, Clausius's researches into the constitution of liquids show that, in the case of individual molecules, such an equilibrium does not exist. Moreover, the conditions of molecular movement at the free surface of the ice are evidently different from those that are within. Hence, the piece of ice must grow, in certain places and in certain directions, at the expense of other of its parts; the increment at one spot corresponding to the decrement at a different one. Two pieces of ice in contact, or even in close proximity, are therefore likely to freeze together.

By freezing water in a flask under a pressure of a decimetre of mercury, solidification was invariably promoted; and it not unfrequently took place in a direction which was definitely related to what may be called a great circle of the flask.

Pressure, however, is not the only source of regelation. According to the author's theory, the phenomenon may result from any *molecular* disturbance.

PHYSIOLOGY

Coagulation of Blood

PROF. MANTEGAZZA cuts the Gordian knot of the cause of the coagulation of the blood, by attributing it to an action of the white corpuscles of the blood. Admitting Schmidt's theory of fibrin being the product of fibrinoplastin and fibrinogen, he puts forward the idea that normal plasma of the blood contains fibrinogen only, but that the white corpuscles have the power, when irritated, of emitting, or we might almost say secreting, fibrinoplastin, and thus of causing coagulation. The shedding of blood, any contact with foreign substances, are causes of irritation to the white blood corpuscles, and hence these things become in turn causes of coagulation. In support of this theory he insists on the complete coincidence of the power of coagulation with the presence of white blood (or lymph) corpuscles; and on the fibrinoplastic properties of tissues, such as cornea, &c., which abound in cells similar at least in nature to white blood corpuscles.—(Ann. di Chim., July 1869.)

THE *Journal of Anatomy and Physiology*, No. 5, November 1869, contains many valuable papers, *e. g.* on the Muscles of the Limbs of the Anteater, &c., by Professor Humphry; on the Movements of the Chest, by Dr. Arthur Ransome; on the Chemical Composition of the Nuclei of Blood Corpuscles, by Dr. Brunton; an abstract of Mr. E. Ray Lankester's Report on the Spectroscopic Examination of Animal Substances; and a long paper by Dr. T. A. Carter, on the Distal Communication of the Blood-vessels with the Lymphatics. The abstracts of Anatomy and Physiology are still continued with the completeness, accuracy, and critical intelligence which render them the best things of the kind to be found anywhere. Dr. Moore, the indefatigable translator from Dutch and other unusual tongues, supplies a translation of a very interesting paper by Engelmann, on the Periodical Development of Gas in the Protoplasm of Living Arcellæ. We may congratulate ourselves on the fact that the journal is able to make its way, in spite of the difficulties with which in this country Anatomy and Physiology have to contend.

SOCIETIES AND ACADEMIES

LONDON

Royal Geographical Society, November 22.—Sir Roderick Murchison in the chair. A paper was read detailing the results of an exploration of the new course of the Hoang-Ho, or Yellow River, made in 1868, by Mr. Elias, a young merchant of Shanghai, illustrated by a map, the positions in which had been carefully laid down from observations taken by that gentleman. The Chinese records, which are very copious in relation to this turbulent river, mention nine changes of its course, dating from 602 B.C. to the last in 1853, during which its outlet has shifted from 34° to 40° north latitude, the present being the former mouth of the river Tsa-Tsing, in the Gulf of Pecheli. The gradual elevation of the bed of the river caused the waters to press against the upper portion of the embankments, and as neither the dykes were raised, nor the bed deepened, the waters effected a breach in 1851, which was enlarged in the following year, till in 1853 the whole stream flowed through the mile-wide breach, in a north and east direction, leaving the old course dry. From this breach at Lung-Menkau, the river flowed in an ancient bed for 52 miles, but from that point a tract 96 miles long was inundated to a width of 15 miles. Ruined houses, broken bridges in the midst of the waters, and the remains of the banks of two canals forming the northern and southern channels, and here and there vast stretches of mud—were all that told of a once fertile and populous district. The deserted houses were in many cases silted up to the eaves by the alluvial deposit. In the dry season fifteen inches of water were scarcely found in some places. At Yushan the waters converged into the bed of the former river, Tsa-Tsing, now usurped by the Yellow River. The Grand Canal crossed this flooded district, but its banks have been carried away and its communication to the north destroyed. Proceeding down, a broken bridge of seventy arches obstructed the stream it could not span. For 150 miles a fertile and garden-like country was passed through, to which succeeded a barren treeless waste, except for the belt adjoining the river, which was fertile and cultivated; the ground, however, even with the growing crops, and in one place the town wall, was undermined and carried away piecemeal by the encroaching river. A barren, marshy tract of reeds, tenanted by wildfowl, extended for about twenty miles from the sea. This change of course, has, it is said, cost the Chinese Empire fifty to sixty millions of its population, the country lying on the old course having been ruined by the drying up of the river, and that in the new by the floods. The new course is unfit for navigation. Vessels drawing six feet of water might cross the bar, and proceed with difficulty to Yushan, but none beyond.—Captain Sherard Osborn remarked that in 1818 the Chinese Censors had called the Imperial attention to the impossibility of effectually controlling the Yellow River; although the expense of the maintenance of the dykes had been quintupled. The maladministration which had resulted in this calamitous change could not, therefore, be chargeable to British interference with China. British engineers, if employed, would soon restrain the Hoang-Ho within due bounds, and utilise its waters for navigation and irrigation. The Chinese water-systems were beginning to be better known, and he hoped that the Upper Yangtse would soon be opened to our steamers, for every forward footstep of Englishmen would, he believed, be a blessing to China.—Mr. Wylie, the first Englishman who saw the results of the diversion of the river from its course, gave an account of his crossing the river bed, then become a sandy highroad covered with passengers, and some particulars of a journey made by him to the sources of the Han River, in which he identified the pass described by Marco Polo as the White Horse Pass.

Royal Asiatic Society, November 15.—This was the first meeting of the Society after the recess. Mr. W. E. Frere occupied the chair. A paper was read containing an Account of the Bheel Tribes of the Vindhya and Satpura Ranges, by Lieut. J. Waterhouse. The writer starts from a popular tradition among those tribes, according to which the originator of the Bheel race is said to have been a vicious and deformed son of Mahadeva, who, on account of his having killed his father's favourite bull, was sent off to the jungle and uninhabited wastes, and told to cultivate where he chose. From this tradition, combined with the well-known legend of the Mahabharata and Shrî Bhagavata, by which the Nishadas are said to have descended from the Rajput king Vena, Mr. Waterhouse concludes that the Bheels had originally been settled in Judhpur and Marvar, but being driven thence by Rajputs, they emigrated southwards and established themselves in the mountains of Malwa and Candeish, in the Vindhya and Satpura ranges, and on the rugged banks of the Nerbudda and Tapti, where, protected by the natural conditions of the country, they had since dwelt, subsisting partly on their own industry, but mainly by inroads into the surrounding plains. Moreover, it was stated in the history of the princes of Judhpur and Oodeypur, that the Rajputs originally conquered their country from the Bheels. These are then divided by the writer into three classes—the Village, the Cultivating, and the Mountain Bheels. The first are said to consist of a few only, who, being scattered over the villages on the plains, were generally considered as honest and trustworthy, and often employed as the watchmen of their villages. The Cultivating Bheels continued to live peacefully in hamlets under the rule of their Turwees, though still preserving traces of a ruder and wilder state, such as was prevalent among the Mountain Bheels, who, owing to the difficult nature of the places inhabited by them, had never been altogether subdued, and subsisted only by plunder. Notwithstanding these distinctions the Bheels were one people, and their different tribes intermarried, though with certain restrictions. Polygamy was the rule with them, and it was by no means uncommon to find men with four or five wives. Many children were born, but a large portion died young, owing perhaps, in a great measure, to the malaria in the jungles, where fever and diseases of the spleen were common. The writer then proceeds to give a brief description of their dress and arms, their language and some of their customs. The Bheels are said to be very vindictive and to keep up feuds for many years, sometimes for generations. "Blood for blood" is their general maxim. The life of a man can, however, be made good to his relatives by payment in kind or money of 120 rupees, or of a woman of 60 rupees. In each community the head Bheel is called Turwee. His office is hereditary, and the police arrangements of the village are carried out by him. On the succession of any of the Rajput chiefs it is considered essential the head Bheel Turwee should make a mark with his blood on the forehead of the chief, without which ceremony no succession is considered complete. By the Rajputs intermarrying with the Bheel women, a race results called Bheelalahs, to which most of the chiefs of the Vindhya Bheels belong. In consequence of their descent from the Rajput conquerors they obtain superior rank and authority among the Bheels, though, as is generally the result of a blending of different races, they seem to combine the viciousness and roguery of the subdued Bheels with the arrogance and haughty bearing of the conquering Rajput. The reading of Mr. Waterhouse's paper was followed by a lively discussion, in which several of the members present took part, who, from a residence in the places occupied by the tribes in question, were able to supply some new and interesting particulars with regard to their dialect and manners. It was then announced by the chairman that the next meeting would be held on Monday the 29th inst.

Royal Horticultural Society. *Scientific Committee*, Nov. 16.—Mr. W. W. Saunders, F.R.S., in the chair. The Rev. M. J. Berkeley exhibited some walnuts, in which the outer rind was completely blackened and shrivelled by frost, the nut in the interior being unaffected. Mr. Glaisher remarked that during winter the temperature of the atmosphere was usually considerably warmer at a level of 20—50ft. above the surface than at a lower altitude. He expressed his opinion that the peculiar appearances presented by the walnuts were due rather to dryness of the atmosphere than to actual frost. Prof. Ansted called attention to the effect of wind in blackening the leaves on one side of a tree, while on the unexposed side they retained their green colour. The chairman stated that an illustration of this fact might recently have been seen in Somersetshire, where the trees for a distance of thirty miles or more were thus affected. Mr. A. Murray then alluded to a peculiar beetle preying on the foliage of orchids introduced from widely diverse countries, and pointed out many interesting facts. Dr. Masters, who spoke on the part of the sub-committee appointed to watch the progress of the plants in the experimental ground at Chiswick, exhibited a series of diagrams, showing in a graphic form the relative degrees of vigour exhibited by the plants at the various dates of observation, and the fluctuations in the intervals between them. Similar tables had been prepared, showing the amount of heat and rainfall during the entire period of observation, and the fluctuations in the intervals between each separate observation. The most striking results shown in the diagrams were as follows:—In almost every case the plants in the unmanured boxes were the least vigorous. The application of purely mineral manures was productive of little or no result in the case of the grasses, but was much more effective in promoting vigour in the case of the clovers. A striking contrast was exhibited in the case of almost all the twelve separate kinds of plants treated with ammonia salts, or with nitrate of soda respectively. It was shown in Dr. Masters' tables that almost invariably when the plants treated with ammonia salts manifested an increased degree of vigour, those treated with nitrate of soda showed a corresponding decrease. These contrasted fluctuations occurred at a time when the weather tables showed a high rainfall and a decreased temperature. Similar antagonistic results, but manifesting themselves at a later period, when the temperature was higher and the rainfall less, prevailed to a less extent in the boxes manured with a combination of mineral manures and nitrate of soda, and of mineral manures and ammonia respectively. Dr. Gilbert remarked that the experiments, as conducted this year, were serviceable rather as indications of what to avoid in the coming year, than for any immediate use at present. The soil made use of was too fertile, and in consequence the plants made undue growth. The contrasting conditions alluded to by Dr. Masters probably depended on variations in the relative power of diffusion of the several salts, and the range of the roots. Nitrate of soda was distributed with great rapidity. The ammonia salts were converted into nitrates before absorption by the plant, and were thus distributed at a lower depth. Dr. Voelcker corroborated Dr. Gilbert as to the necessity of caution in drawing general inferences from this season's experiments, and advised that in future the plants should be grown in pots, so as to be more under control, and less subject to disturbing influences. Mr. Glaisher alluded to the effects produced by the roots of plants in increasing the temperature of the soil, and suggested that a thermometer should be inserted into each of the seventy-two boxes. These thermometers, moreover, should be made with great care, and the mercury in all should be derived from the same source, so as to secure uniformity of expansion.—A report from Mr. Barron, on various experiments that have been carried on as to grafting on various stocks, was then read. The results had been very varied, and were of a very interesting character. In those cases where failure had resulted, the want of success was attributed to one or more of the following causes:—Imperfection in the mode of operating; the too advanced condition of the stocks or of the buds before the operation; the want of correspondence in point of time between the growth of stock and scion, &c. This report will be published *in extenso*.—A communication from Mr. Barber, forwarded by Dr. Hooker, relating to the culture of Aloes, was then read. The Chairman remarked that the rocky nature of the country in which Aloes grew was serviceable in preventing excessive or long-continued moisture. He had ascertained from Mr. Cooper that many of the Haworthias grew naturally closely environed by herbage, and that when this was eaten by the sheep the plants became unduly exposed to the sun, and died in consequence; hence the sheep were only indirectly injurious (not directly, as Mr. Barber had stated) by removing the herbage. Mr. Saunders in practice substituted a fold of thin paper or muslin for the grass, and thus tempered the light, to the great advantage of the plants.—A report from Mr. Moore on the experiments carried out at Chiswick with various chemical manures on variegated zonal and other *Pelargoniums*, with a view to ascertain the effect of the manures on the colouration of the leaves and the production of flowers, was then read.—A lengthy communication on the cultivation of Tea, by Mr. McPherson, was laid on the table, on which the secretary was instructed to report to a future meeting.—Dr. Masters exhibited, on the part of Mr. D. T. Fish, a sample of soil in which there was a thin layer of lime about six inches below the surface. This had evidently been put on as a top-dressing. Mr. Fish attributed the position of the lime beneath the surface to an annual superposition of a layer of carbonaceous matter on the surface, and to the decomposition of the roots. He advanced this view in opposition to that of Mr. Darwin, who attributes similar effects to the agency of worms. Dr. Voelcker remarked that lime so applied was always washed down gradually in the manner described.

Ethnological Society, Nov. 23.—Prof. Huxley, F.R.S., President, in the chair.—Dr. G. W. Leitner gave an account of his visit in 1866 to Ladak, Little Tibet, Kashmere, and the unvisited country of Ghilghit. He succeeded, by a new route crossing the Shingun and Maraug, in reaching Ladak six weeks before the usual passes were open. The Abbot of Pugdal—the Buddhist monastery where Csoma de Körös spent five years—agreed with him to secure the safe passage of any English or Hungarian traveller to Lassa; offering to give a near relative of his own as hostage for the safety of the visitor. The Punjab Government having commissioned him to obtain information respecting the Chilasi people, with a view of tracing a connection between them and the Darada, and the Hindu Olympus, the Kaylas, he crossed the frontier and penetrated into Ghilghit, four marches beyond any previous European travellers. Out of fifty, only two of his followers accompanied him to the country of the dreaded Dards. Dr. Leitner gave an account of the legends of this people, whom he judges to be a remnant of the most ancient Aryan stock, speaking a highly inflexional and perfect, though unwritten language, and preserving ancient mythologies and traditions of their origin. A singular exception to the Dard dialects is found in the Khajuna spoken by the Hunza people—the robbers of Kunjut—and Nagyr, which is like no other known language. Dr. Leitner has brought a large collection of Thibetan and Dard curiosities, and an intelligent Yarkandi, who as soldier and trader has traversed nearly all Eastern Turkistan: it is to be hoped that he may be given, during his stay in England, opportunities of learning something of our manufactures and commerce, so that he may carry back to Yarkand a good report of English power, and, we will add, of English hospitality and friendship, which will assuredly bear good fruit in the future conduct of the Yarkandis, who are already well disposed to receive and trade with our countrymen.

Entomological Society, November 15.—Mr. H. W. Bates, President, in the chair. The following gentlemen were elected: Messrs. French and Websdale as members; and Messrs. Barnes, Brown, E. M. Janson, O. E. Janson, Pearson, and Robinson, as subscribers. Exhibitions of insects were made by Messrs. F. Smith, Pascoe, Briggs, Davis, and Salvin; and the discussion which ensued thereon was participated in by the President, Messrs. Westwood, Wallace, Müller, Weir, Janson, McLachlan, Eaton, Wormald, Horne, Verrall, and Dunning. The following papers were read:—"New Genera and Species of *Coleoptera* from Chontales, Nicaragua," by the President. "Description of New Genera and Species of *Hispidæ;* with notes on some previously-described species," by Mr. J. S. Baly. "A Synopsis of the Genus *Clothilda,*" by Mr. Osbert Salvin.

Statistical Society, November 16. — A large body of Fellows assembled to hear the President, Mr. W. Newmarch, F.R.S., deliver his inaugural address, in which he reviewed the progress that had been made in statistical science since the foundation of the Society in 1834. He pointed out that at that time, with perhaps two or three partial exceptions, foreign Governments and Legislatures had not arrived at even the faintest notion of the desirableness of systematic statistical evidence, but that during the last twenty-five years this state of things had almost disappeared, and in several foreign states there were now in full activity statistical departments, and a vigour of statistical research by independent persons, that almost reduced the United Kingdom to a second place. Having enumerated the branches of inquiry in which this country had made most decisive and gratifying progress during the last thirty-five years, he stated that the following fields of statistical research seemed to him to require early attention:—1. The annual consumption per head among different classes, and by the nation as a whole, of the chief articles of food—corn, butchers' meat, tea, coffee, sugar, tobacco, wine, spirits, and beer. 2. The annual production in agriculture, minerals, metals, ships, and manufactures. 3. The comparative wages, house-rent, and cost of living in different parts of the country. 4. The total annual income and earnings and the total annual accumulations of different classes, and of the country as a whole. 5. The relative taxation of different classes in this country, as compared with the same classes in those foreign countries, the competition of which England has to understand and meet—carefully attending in the inquiry to the comparative merits of direct and indirect taxation. 6. The financial and economical cost and burdens entailed by extensive warlike armaments. 7. Periodical statistics of public hospitals in the metropolis and larger towns, with a view to the comparison of the efficiency and cost of the relief afforded in each. 8. Periodical returns of the income and operations of charitable trusts and endowments, for relief and education. 9. A statistical ascertainment of the numerical strength of the different religious churches and sects. 10. Statistical evidence of the cost to the community in sickness, excessive mortality, and poor-rate expenditure of defective dwellings, and sanitary regulations. 11. Statistical evidence of the gain to the community of instruction in popular schools in the rudiments of political economy, in the commoner industrial arts, and in military exercises. 12. Statistical evidence of the consequences in this country of the emigration from it. 13. Investigations relative to the advantages and cost to this country of the occupation of India. 14. An investigation on grounds of fact of the effect of commercial treaties, especially of the French Treaty of 1860. 15. A similar investigation of the consequences produced in the United States by the rigid system of protective tariffs. 16. And by the protracted suspension of specie payments. 17. Statistical inquiries relative to the effects produced in Europe on commerce, accumulation, invention, prices, and the rate of interest, by the gold discoveries in California and Australia. 18. Investigations of the mathematics and logic of statistical evidence; that is to say, the true construction and use of averages, the deduction of probabilities, the exclusion of superfluous integers, and the discovery of the laws of such social phenomena as can only be exhibited by a numerical notation.

DUBLIN

Royal Dublin Society, November 15.—The first meeting of the 139th session. Mr. W. Andrews read a paper on Deep-Sea Soundings. The author stated that he did not mean to refer to the deep-sea dredgings of the *Lightning* and *Porcupine,* but to some soundings of his own, extending to the moderate depths of eighty fathoms off the Blasquet Islands, on the west coast of Ireland, which were chiefly undertaken in connection with the subject of Irish fisheries. There was a rock near Dingle harbour known as the Barrack Rock to the fishermen, the position and bearings of which had never been determined, no notice of it appearing in the corrected charts of 1860. In July of the present year he had succeeded in taking its bearings and soundings; at low water and at extreme springs there are barely three fathoms covering the rock, and yet in the charts the soundings over it were marked at from 38 to 40 fathoms. The author then proceeded to notice some of the more interesting animals taken by him off the west coast of Ireland during this and other soundings; such as, *Paracyathus taxilianus* and *P. thulensis,* the animals of which he had examined [these two species were first described by Gosse, from single Scotch specimens, and the animals belonging to them were up to the present unknown]; *Eschara foliacea,* which he inclines to think is very different from the true *Millepora cervicornis,* which latter coral he took living in 39 fathoms off the little Skellig Island. [*E. foliacea* is not uncommon off the west coast of Ireland; but we suspect some strange mistake here, as *Eschara* is a well-known genus of the Polyzoa, whereas *Millepora* is almost without doubt a *Hydrozoön,* and has never yet been met with, we believe, north of a mean winter temperature of the sea of 66° F.]

Mr. W. F. Kirby read an account of a natural history excursion made to the continent of Europe in the spring of the present year, detailing his captures at Hilden, Basle, the Righi, St. Gothard, and the Val da Foin.—Mr. A. G. More read an account of an excursion, zoological and botanical, to Connemara, county Galway.—Mr. H. Grubb gave an account of a remarkable meteor seen in the heavens over Dublin between 6 and 7 o'clock, P.M., on the 6th inst.

Royal Irish Academy, November 8.—The first meeting of the present session. The council announced that Lord Talbot de Malahide had, owing to his intended sojourn abroad for the winter and spring months, sent in his resignation of the office of President; this resignation was, with regret, accepted. Of the names of those mentioned as likely to succeed to the post, that of the Earl of Dunraven would appear to be the most popular. A paper was read by Mr. G. H. Kinahan on the ruins of Ardillaun, county Galway.

The following numbers of the Transactions have been published since the session closed in July.—Mr. W. Andrews on *Ziphius Sowerbyi.* [Trans. vol. xxiv. Science, part X.]—Prof. W. King on the Histology of the Test of the class Palliobranchiata. [Trans. vol. xxiv. Science, part XI.]—John Casey, A.B., on Bicircular Quartics. [Trans. vol. xxiv. Science, part XII.]—Professor E. Perceval Wright, contributions toward a knowledge of the Flora of the Seychelles, with four plates. [Trans. vol. xxiv. Science, part XIII.]

MANCHESTER

Literary and Philosophical Society, November 2.—J. P. Joule, LL.D., F.R.S., &c., President, in the chair. William Boyd Dawkins, M.A., F.R.S., and Thomas Edward Thorpe, Ph.D., were elected ordinary members of the Society. Professor H. E. Roscoe, Ph.D., F.R.S., presented a paper on a new Chromium Oxychloride, by T. E. Thorpe, Ph.D., assistant in the laboratory of Owen's College. When chromyl dichloride, CrO_2Cl_2, prepared by heating a mixture of potassium dichromate, sodium chloride, and sulphuric acid, is maintained at a temperature of 180°—190° C. in a sealed tube for three or four hours, it is almost completely converted into a black solid substance, and on opening the tube when cold a considerable quantity of free chlorine escapes. By exhausting the tubes containing the liquid chloride before subjecting them to heat, the author ascertained that chlorine was the only gaseous product of thi decomposition. The black compound invariably contained mor or less of the liquid chloride which had escaped decomposit on; the greater part of this was easily expelled on gently heatin the mass after opening the tube. In order to free it completely from the latter body the black substance was transferred to a clean tube, and heated to 120° C. (*i.e.* about 2° above the boiling point of chromyl dichloride) in a current of dry carbonic acid gas until its weight appeared constant. A determination of the amount of chlorine contained in the volatile portion showed that it was simply chromyl dichloride which remained undecomposed. The solid substance, dried in the manner above described, appeared as a black uncrystalline powder, which, when exposed to the air, rapidly deliquesced to a dark reddish brown syrupy liquid, smelling of free chlorine. When thrown into water it quickly dissolved, forming a dark brown solution, which, on standing, also evolved chlorine. In nitric acid solution hypochlorous acid appeared to be produced. In strong hydrochloric acid the substance dissolved with a dark brown colouration, and on boiling the solution chlorine was evolved, the liquid became greenish yellow, and ultimately changed to the dark green colour, peculiar to a solution of chromium sesquioxide in hydrochloric acid. When thrown into dilute ammonia, chromic acid was dissolved, together with all the chlorine, and a precipitate was formed, possessing the properties of the chromate of chrome sesquioxide ($Cr_2O_3CrO_3$) described by Storer and Eliot. Upon this decomposition is based the method which the author employed for the estimation of the amount of chlorine contained in this body. The weighed quantity of the substance was treated with very dilute ammonia, the solution boiled for a few minutes, filtered, the precipitate well washed by hot water, an excess of nitric acid added to the filtrate, and the chlorine precipitated by the addition of silver nitrate. Two determinations of chlorine, carried out in this manner on preparations made at different times, gave 21·06 per cent. of chlorine as the mean. In order to determine the amount of chromium, a weighed portion of the substance was repeatedly heated with strong hydrochloric acid on a water-bath until the evolution of chlorine entirely ceased; the solution was then diluted with water, heated to boiling, ammonia added in slight excess, and again boiled until the supernatant liquid appeared perfectly colourless. The precipitated chrome sesquioxide was then filtered, dried, and weighed. The mean of two determinations indicated 48·91 per cent. of chromium. These results come very near to the percentage composition calculated for the empirical formula $Cr_3O_6Cl_2$. In conformity with the analytical results, the new oxychloride may be regarded as a compound of chromous chloride with two equivalents of chromium trioxide, and represented by the formula $CrCl_2 2CrO_3$, analogous to the formulæ assigned by Péligot to a series of chlorochromates. Experiment, however, led the author to believe that the constitution of his chromium chlorochromate, and of the salts described by Péligot, is not correctly represented by such formulæ, and in his paper he gives elaborate structural formulæ, which seem to him to agree better with experimental facts, and to show the relation of these compounds to chromyl dichloride.

PARIS.

Academy of Sciences, November 15.—M. E. Becquerel communicated the fifth memoir of his researches upon the luminous effects resulting from the action of light upon bodies, containing his investigation of the influence of the waves of light of different refrangibilities. His paper, which is of the greatest interest and importance to physicists, describes his experiments upon the behaviour of a number of phosphorescent bodies in various parts of the spectrum. No idea of its contents could be given in a short abstract, but we shall probably revert to it on another occasion.—In a note on "The Explosions of Bolides and the Falls of Aerolites which accompany them," M. Delaunay suggested that the explosion of a bolide is caused by the pressure of the atmosphere in front of it taking advantage of any irregularities in the structure of the body, the latter being probably, in many cases, caused or increased by the influence of the great superficial heat. The same atmospheric pressure, in M. Delaunay's opinion, stops the onward motion of the detached fragments, which then fall to the ground. The black crust of the surface of aerolites was ascribed by the author to the passage of the fragments at the moment of their being detached through the compressed and heated air. General Morin remarked upon the compression of the air in front of projectiles and below falling bodies.—M. Chapelas presented a note on the meteors of November 1869, in which he stated that on the 12th and 13th of this month the number of meteors observed was—on the 12th, 6·8, and on the 13th 24·8, per hour. The maximum occurred in the early part of the night.—A notice of the partial explosion of a bolide by M. J. Silbermann was communicated. This meteor was observed on the 11th November, at 10·55 p.m., in the constellation of Ursa Major. It descended obliquely towards the horizon N.N.E. of Paris, and passed through a space of about 34°. Its trajectory, at first nearly straight, soon became undulated between the stars ψ and ω, *Ursæ Majoris;* its rapidity of movement diminished considerably, and a violent explosion took place, the apparent volume and brilliancy of the body having previously increased greatly. After the explosion it continued in a straight course for some distance. The explosion was very brilliant, and sparks were scattered in all directions. The author concluded that this explosion was only partial. M. H. Lartigues, who also observed this meteor, spoke of it as having disappeared after dividing into fifteen or twenty fragments. He described some of these as coloured, which was denied by M. Silbermann; and the latter gives the meteor a duration of at most $1\frac{3}{4}$ seconds, whilst according to M. Lartigues it was visible for four seconds.—M. H. Sainte-Claire Deville presented the correction of an error in the formulæ for calculating the co-efficients of dilatation in some of his memoirs.—M. E. J. Maumené communicated some facts observed with regard to inverted sugar. The author stated that inverted sugar consists not of equal quantities of glucose and levulose, as supposed by Dubrunfaut, but of 12·14 of the former and 87·86 of the latter. Crystals of glucosate of sodium-chloride obtained from inverted sugar, presented the same composition and primitive crystalline form as crystals obtained from diabetic sugar, but their solution effected what M. Maumené calls the *deversion* of the rotatory power in an hour and three-quarters, whilst the solution of the same compound prepared from diabetic sugar requires seven hours to produce the same effect. The author also remarked upon some other points connected with inverted sugar and the glucosate of sodium chloride.—Of two geological papers presented to the meeting, the first was by Mr. Gaston Planté on "The Lower Lignites of the Plastic Clay of the Paris Basin." The author described a section near Meudon, where the lower lignite beds had been exposed. It showed in descending order—(1) the lower beds of the *Calcaire grossier;* (2) a bed of plastic clay with a black lignitiferous vein (the upper lignite bed); (3) a red marbled clay bed; (4) a dark clay bed containing lignites (the lower lignite bed); and (5) conglomerate. The lower lignite beds furnished parts of the lower jaw of *Crocodilus depressifrons* (Blaino), and a femur belonging to the same species; two vertebræ, probably of *Coryphodon;* and the lower extremity of a bone, probably the humerus of a mammal, having the whole of the osseous tissue converted into gypsum in small crystals. The bed contained numerous coprolites of crocodiles. The subjacent conglomerate furnished numerous fossils, including teeth and fragments of crocodiles and mammals, portions of tortoises, and scales of *Lepidosteus.* The teeth of mammalia appear to indicate the genera *Coryphodon, Palæonictis,* and *Pachynolopyus.*—The second geological paper was by M. E. Guignet, and treated of the chemical composition and formation of the beds of the great oolite and forest marble of the Haute Marne. The author discussed the distribution of these formations and the influence exerted by their presence upon agriculture.—M. Croullerois presented a note on a "Theorem of Electro-Dynamics and the Explanation of an Electrical Phenomenon;" and M. Milne Edwards four notes on some zoological observations made in his laboratory at the Museum.—In the first of these, M. Jobert described the structure and anatomical relations of the nasal glands in birds; the second, by M. Oustalet, contained a minute description of the respiratory organs in the pupæ of dragon-flies; the third consisted of observations on the salivary glands of *Myrmecophaga tamandu,* by M. J. Chatin; and the fourth was an anatomical and zoological investigation of the species of the genus *Equus* allied to the *Hemione,* by M. George.—A letter from Mr. A. Mayer, accompanying his photographs of the late total eclipse of the sun, was communicated by M. Delaunay.—M. E. Mathieu presented a memoir on the equation with partial differences of the fourth order $\Delta \Delta u = 0$, and on the equilibrium of elasticity of a solid body.—A portion of a letter from M. E. Duclaux was read, in which he announced that by exposing the eggs of silkworms to cold in August, he had caused an early development of the embryos, which were hatched in November.

—M. E. Prillieux described some experiments by which he has demonstrated that etiolated plants acquire their healthy green colour more rapidly when shaded than when exposed to the direct rays of the sun.—M. L. Colin communicated a note on the etiology of intermittent fevers, or "telluric intoxication," in which he ascribed them entirely to the toxical action of the soil, and declared that residence in large cities has a remarkable prophylactic effect.—Several other notes, of which only the titles are given, were read.

VIENNA

Imperial Academy of Sciences, October 21.—A memoir was communicated from Dr. W. F. Gintl on Ratanhine and its Compounds.—Dr. F. Steindachner presented a report on a collection of fishes made by Baron Ransonnet, at Singapore. The collection contained 60 species, some of them of particular interest, as having been previously obtained only from Japan or Eastern Africa. Four species were described as new, belonging to the genera *Platyglossus* (2), *Pseudochromis*, and *Gerres*.—A memoir, on the origin of the fatty oil in the olive, by M. C. O. Harz, was presented, in which the author states that at first this secretion does not possess the properties of a fatty oil, but its constituents are surrounded by a membrane, and therefore represent true secretion-cells, until the approach of maturity. These secretion-cells are not simple vesicles, but contain numerous daughter-cells, which, with the membrane of the mother-cell, all finally become converted into oil. The presence of the membrane is best demonstrated by treatment with Miller's Salt solution of aniline and chloriodide of zinc successively; the membrane acquires a fine dark-blue colour.—The table of meteorological and magnetical observations at the Central Observatory for the month of September was presented.

November 4.—M. F. Maly communicated a memoir entitled Theorems upon Straight Lines in Space.—Dr. Fitzinger presented the concluding part of his memoir on the cynopterine family of bats; and Dr. A. Boué made some remarks on the geography of the basins of the Drin and Vardar in North Albania and Macedonia.

November 11.—Prof. Lang communicated a memoir describing an experimental investigation of the velocity of light in quartz. Quartz, unlike other uniaxial crystals, possesses a doubly refractive power in the direction of its longitudinal axis. The author has already stated theoretically that in quartz there is no ordinary undulation, and even the extraordinary undulation changes according to a different law from that prevailing in the ordinary uniaxial crystals. His present paper contains the observational proof of this theoretical result. Dr. C. Jelineck reported upon a self-registering thermometer, constructed by M. Hipp, of Neuchâtel. Dr. F. Steindachner presented the first part of his ichthyological report upon a journey to Senegambia. It referred to the brackish-water fishes of the Senegal, and contained descriptions of 21 species, most of which are among the greatest rarities in European museums, and several of them are only known from the Guinea coast. The species belong to the families *Percidæ*, *Pristipomatidæ*, and *Carangidæ*. The author stated that *Otolithus senegalensis* is identical with *Pseudolithus typus* (Bleek.), *Pristipoma macrophthalmum* (Bleek.) with *Larimus auritus* (Cuv. and Val.), *Trachynotus myrias* and *maxillosus* with *T. goreensis* (Cuv. and Val.), and *Trachynotus goreensis* (Bleek.) with *T. ovatus* (Lin.), and that *Pristipoma Rangii* (Cuv. and Val.) is only a young form of *P. suillum* of the same authors.—Prof. Ditscheiner communicated a note upon the dispersion of the optic axes in rhombic crystals, in which he showed that both the true and the apparent angle of the optic axes may be represented by Cauchy's dispersion formula:—

$$\frac{\phi}{2} = A + B\frac{1}{\lambda^2}$$

as a function of the wave-length λ. The table of observations for the month of October, at the Imperial Central Institution for meteorology and terrestrial magnetism, was communicated.

BERLIN

German Chemical Society, November 8.—The following papers were read.—Schultsen and Nenky on the formation of Urea in the Body.—Liebreich on an Antidote against Strychnia.—Oppenheim on Iodo-bromide of Mercury.—Baeyer: Remarks on Thomsen's Criticism of Hermann's Calculation of the Heat of Combustion.—Hoffmann on some Derivatives of Sulphuretted Ureas.—Von Somaruga on Cresylopurpuric Acid.—Weidel on Sandal-wood.—Weselsky on Double Cyanides.—Thomsen (1) on the Preparation of the Hydrate of Chloral; (2) on Selenious and Selenic Acids.—Henry on Ethylated Derivatives of Alcohols and of Polyatomic Acids.—Henry on the Preparation of Pure Iodine from Iodide of Mercury.—Henry and Radzicewsky: Correction of a Former Note on Paratoluidine.—Friedel: Scientific Correspondence from Paris.—Merz and Weith on a new method of forming Triphenylated Guanidine.

PHILADELPHIA

Academy of Natural Sciences, May 4.—A paper entitled "A Review of the Species of Plethodontidæ and Desmognathidæ," by E. D. Cope, was presented for publication.—Mr. J. H. Redfield stated that on the 22nd of April, in company with Mr. C. F. Parker, he had visited Cedar Bridge, Ocean County, New Jersey, in search of *Corema Conradii*. This plant occurs in Newfoundland, on islands near Bath, Maine, at Plymouth, Cape Cod, and near Islip, Long Island, and was first discovered at Cedar Bridge by Prof. S. W. Conrad. This locality was visited by Dr. Long about 1835, and carefully indicated by him in Ann. N. Y. Lyc. Nat. Hist. iv., 83, so that there was no difficulty in finding the precise points mentioned; but Mr. Redfield was sorry that no trace of the plant could be found there; and it has doubtless been eradicated by animals or by unscrupulous collectors, or has been otherwise unable to maintain its foothold in "the struggle for existence." The vicinity also was carefully examined, but without success. The plant is said to have once existed near Pemberton Mills, New Jersey; but as that neighbourhood is now entirely under cultivation, there is no evidence that the *Corema Conradii* now exists south of Long Island. If it is again to be discovered in New Jersey, it will probably be in the wide sandy waste a few miles west of Cedar Bridge, near the boundary between Burlington and Ocean counties, where a succession of elevated ancient ocean beaches offer conditions similar to those of Cape Cod.—Prof. Cope exhibited bones and teeth of a large extinct Chinchilla of the island of Anguilla, West Indies, *Amblyrhiza inundata;* and with them teeth of a second and new species, which he called *Loxomylus longidens.* It was also allied to the Chinchillas, and of large size. They were accompanied by a shell implement of human manufacture, which was (so far as discovery in earthy matrix, the colour, &c., were evidence) of the same age as the Rodent.

May 11 and 18.—The following papers were presented for publication:—"Further notes on Microscopic Crystals"; by Isaac Lea, LL.D.—"Sexual Law in the Conifera"; by Thomas Meehan.—"An attempt to ascertain the average weight of the brain in the different races of mankind"; by Joseph Barnard Davis.

June 1.—Prof. Cope exhibited some interesting specimens of extinct reptiles; one of these was the cranium, minus a portion of the muzzle of a gavial, from the New Jersey Greensand, previously described under the name of *Thoracosaurus brinispinus*, but which this specimen demonstrated to belong to another genus, since it did not present the lachrymal foramina of the former. He applied the name *Holops* to it, and stated that he had evidence that *Crocodilus tenebrosus* Leidy, and probably *C. obscurus* L. also belonged to it. He also exhibited drawings, with measurements of portions of the limbs, of a very large Dinosaur, in the collection of Dr. Samuel Lockwood, of Keyport, Monmouth county, New Jersey. It was discovered by this gentleman in the lower cretaceous clays on the shores of Rassitan Bay. It consisted of the extremity of the tibia, with astragalus and fibula. He said it indicated the second genus of his suborder Symphypoda, and was thus allied to Compsognathus, differing in the remaining indication of suture between astragalus and tibia, which disappeared in Compsognathus. The astragalus thus entirely anchylosed was also confluent with the calcaneum, forming a continuous condyloid surface for the tibia. In an anterior projection externally, the extremity of the fibula reposed by a condyloid extremity, the shaft lapping over the outline of the tibia. This demonstrated what he had already stated, that the fibulæ of Iguanodon and Hadrasaurus had been reversed. The length of the fragment was sixteen inches, the fractured section was a transverse oval, the medullary cavity nearly filled with cancellous tissue. The transverse width of the extremity 12 in.; oblique diameter 14 in. This form he called *Ornithotarsus immanis*, and placed it between Hadrasaurus and Compsognathus. It indicated one of the most gigantic of the Dinosaurs yet discovered. He made some observations on a fine fragment of the muzzle of a large Mosasauroid, which pertained to a cranium of near five feet in length. The pterygoid bones were separated from each other, and support nine teeth. A peculiarity of physiognomy was produced by the cylindric prolongation of the premaxillary bone beyond the teeth, and a similar flat prolongation of the extremity of the dentary. He referred the species to *Macrasaurus* Owen, under the name of *M. pririger*. The specimen he stated belonged to Prof. Agassiz, who obtained it from Western Kansas, probably from the No. 3 of the Upper Cretaceous of Hayden. The following paper was presented for publication:—"Description of new Carboniferous Fossils from the United States"; by F. B. Meek and A. H. Worthen.

June 8.—The following paper was presented for publication: "On the production of Bractæ in *Larix*"; by Thos. Meehan.

June 22.—The following paper was presented for publication: "Notice of certain obscurely known species of American Birds, based on specimens in the museum of the Smithsonian Institution"; by Robert Ridgway.

June 29.—The report of the Biological and Miscroscopical Section was presented, and referred to the Publication Committee. On permission being granted, Mr. Warner spoke upon the mathematical representation of organic forms. Such limitations, he said, might seem to narrow the field of research into the physical causes of organic forms, and perhaps furnish the suggestion of a rational theory of these causes. If no other advantage were desirable from investigations of this kind, they might, he thought, be useful for description and classification. He exhibited a representation of the longitudinal section of an egg by a curve which he called the hyper-ellipse, and of the section of an embryo by another curve, which he termed a deformed lemniscate. Of the egg curve he said that it very closely resembled an ideal section of an egg, taken from a standard modern work. Of the curve representing the embryo he said that it not improbably marked the boundary of matter lying within it in a different state of temperature, density, or tension from the matter lying without. These representations were verified by the members present. The speaker expressed the intention of making these representations the subject of a future paper, in which he would give drawings and formulæ.

July 18.—Mr. Thos. Meehan presented leaves of the peach and cherry, and said it had fallen to him to point out that the leaf-blades of plants were developed in proportion as vigorous vitality was released, and that they were adherent or decurrent in proportion as vigorous vitality was thoroughly developed in the central axis or stem. By following out the same line of observation he had discovered the law which governed the production of sexes in plants, and he now wished to call attention to the operation of the same cause in the production of glands on the leaf-stalks of the peach and cherry. A careful examination of the gland-bearing variety of either of these would show that these glands were simply germs of the cellular matter which formed the leaf-blade. They might be seen in every stage of development, from dense full globes on the petioles to very small dots on the apex of the tolerably well-expanded matter, and it would be further seen that in proportion as vitality was weak were these germs and glands developed. Leaves from the shaded centre of the tree, or from shoots weak or enfeebled from any other cause, produced glandless leaves, while the stronger the shoot the stronger and more numerous were the glands or undeveloped parts. Remembering that these glands were but undeveloped leaf-blades, and that it had been previously proved by the author that plants developed these less freely in proportion to a vigorous axial or stem growth, it should necessarily follow that a weakened vitality would be indicated by an absence of glands. That this was so in the cases referred to, the weak and glandless leaves showed. The author had had a very remarkable confirmation of these recent physiological discoveries. Many varieties of peaches have no glands, and these had been found by the growers of southern Illinois, as he was informed by Dr. Hull, of Alton, in all cases to be the first to succumb to diseases or unfavourable circumstances. It was very seldom that the developments of science and untutored observations went along together, and so thoroughly accorded. To the author it was one of the most interesting facts he had met with in support of his theory, that the degree of separation of the leaf-blade from the main stems was wholly a question of vitality.—Mr. Meehan exhibited some fibre obtained from Mr. Roezel, of Vera Cruz, which was finer and stronger than that furnished by the "Ramie." Mr. Roezel obtained it from a plant which he had found in the Alleghanies, and which he believed to be a new species of Boehmeria. Mr. Meehan had, however, since found it abundantly along the Missouri River, and it proves to be only *Urtica purpurascens*, Nuttall.

EDW. D. COPE, *Corresponding Secretary.*

DIARY

THURSDAY, NOVEMBER 25.

ROYAL SOCIETY, at 8.30.—Preliminary Report of the Scientific Exploration of the Deep Sea in H.M. surveying vessel *Porcupine*, during the summer of 1869, conducted by Dr. Carpenter, V.P.R.S., Mr. J. Gwyn Jeffreys, F.R.S., and Prof. Wyville Thompson, LL.D., F.R.S. (conclusion). Spectroscopic Observations of the Sun; No. 5: J. N. Lockyer, F.R.S. Researches on Gaseous Spectra in Relation to the Physical Constitution of the Sun, Stars, and Nebulæ. Note 3: Dr. Frankland, F.R.S., and J. N. Lockyer, F.R.S. And other papers.

SOCIETY OF ANTIQUARIES, at 8.30.—Ancient British Barrows of Wiltshire and the adjacent counties: J. Thurnam, M.D., F.S.A

ZOOLOGICAL SOCIETY, at 8.30—Notes on some Spiders and Scorpions from St. Helena, with descriptions of new Species: Rev. O. P. Cambridge. On a small collection of Birds from the Tonga Islands: Dr. O. Finsch and Dr. G. Hartlaub.

MATHEMATICAL SOCIETY, at 8.

LONDON INSTITUTION, at 7.30.—Architecture: Prof. R. Kerr.

PHILOSOPHICAL CLUB, at 6.

FRIDAY, NOVEMBER 26.

QUEKETT MICROSCOPICAL CLUB, at 8.

SATURDAY, NOVEMBER 27.

ROYAL BOTANIC SOCIETY, at 3.45.

MONDAY, NOVEMBER 29.

INSTITUTE OF BRITISH ARCHITECTS, at 8.

INSTITUTE OF ACTUARIES, at 7.—Translation by Mr. Bumsted of "Suggestions for a Law to regulate the Calculation and Investment of the Reserve in Life Assurance Companies:" Herr Hopf.

MEDICAL SOCIETY, at 8.

ROYAL ASIATIC SOCIETY, at 3.

LONDON INSTITUTION, at 4.—Elementary Physics: Prof. Guthrie.

TUESDAY, NOVEMBER 30.

ROYAL SOCIETY, at 4.—Anniversary.

INSTITUTE OF CIVIL ENGINEERS, at 8.—Renewed Discussion upon Mr. Gandard's paper on the Strength and Resistance of Materials. On the Public Works of the Province of Canterbury, New Zealand: Mr. Edwd. Dobson, Assoc. Inst. C.E.

ANTHROPOLOGICAL SOCIETY, at 8.—The Shina People (described for the first time): Dr. G. W. Leitner.

WEDNESDAY, DECEMBER 1.

PHARMACEUTICAL SOCIETY, at 8.

OBSTETRICAL SOCIETY, at 8.

THURSDAY, DECEMBER 2.

LINNEAN SOCIETY, at 8.30.

CHEMICAL SOCIETY, at 8.30.

BOOKS RECEIVED

SCIENCE REFORM

A MOVEMENT has been for some time on foot, of a character so important to the Science of England, that we can no longer delay consideration of its object and prospects. It is proposed to submit to a Royal Commission the entire question of the relation of Science to the State; both what now is, and what should be, that relation.

In order to centre the attention of the scientific world on the leading features of the proposed inquiry, we will confine this present opening of the subject, as much as possible, to a narrative of the events which have brought the movement to its present stage.

At the meeting of the British Association at Norwich in 1868, a paper was read by Lieut.-Colonel Strange, in the Mathematical and Physical Section, entitled, "*On the Necessity for State Intervention to Secure the Progress of Physical Science;*" an abstract of which was published in the Report of the Association of that year. Colonel Strange stated verbally that he desired to be considered as merely putting into language the thoughts which had long occupied the minds of many eminent men of science. No one who mixes much in the scientific circles, indeed, can fail to recognise in his paper ideas which, in one form or other, have for some years been gathering strength. Discussion followed the paper, but, as might be expected, it branched off into many of the innumerable details which are involved in so large a question. A practical result, however, was arrived at by the Section, namely, that a committee should investigate the whole matter during the recess, and report to the Association at its next meeting.

This committee accordingly presented its report to the Association this year, at its late meeting at Exeter; and, since the future steps that may be taken must be based, more or less, on this document, we cannot do better than here print it *in extenso*.

The Recommendation adopted by the General Committee at the Norwich Meeting was, that Lieut-Col. Strange, F.R.S., Professor Sir W. Thomson, F.R.S., Professor Tyndall, F.R.S., Professor Frankland, F.R.S., Dr. Stenhouse, F.R.S., Dr. Mann, F.R.A.S., Mr. Huggins, F.R.S., Mr. Glaisher, F.R.S., Professor Williamson, F.R.S., Professor Stokes, F.R.S., Professor Fleeming Jenkin, F.R.S., Professor Hirst, F.R.S., Professor Huxley, F.R.S., and Dr. Balfour Stewart, F.R.S., be a Committee* for the purpose of inquiring into, and of reporting to the British Association the opinion at which they may arrive concerning the following questions:—

I. Does there exist in the United Kingdom of Great Britain and Ireland sufficient provision for the vigorous prosecution of Physical Research?

II. If not, what further provision is needed? and what measures should be taken to secure it?

and that Dr. Robert James Mann be the Secretary.

The Report was as follows:—

Your Committee, having sought the counsel of many of the most eminent men of science of the United Kingdom upon these questions, so far as it was found practicable to do so, and having carefully deliberated thereon, have arrived at the following conclusions:—

I. That the provision now existing in the United Kingdom of Great Britain and Ireland is far from sufficient for the vigorous prosecution of Physical Research.

II. It is universally admitted that scientific investigation is productive of enormous advantages to the community at large; but these advantages cannot be duly reaped without largely extending and systematising Physical Research. Though of opinion that greatly increased facilities are undoubtedly required, your Committee do not consider it expedient that they should attempt to define categorically how these facilities should be provided, for the following reason:—

Any scheme of scientific extension should be based on a full and accurate knowledge of the amount of aid now given to science, of the sources from which that aid is derived, and of the functions performed by individuals and institutions receiving such aid. Your Committee have found it impossible, with the means and powers at their command, to acquire this knowledge. A formal inquiry, including the inspection of records to which your Committee have not access, and the examination of witnesses whom they are not empowered to summon, alone can elicit the information that is required; and, as the whole question of the relation of the State to Science, at present in a very unsettled and unsatisfactory position, is involved, they urge that a Royal Commission alone is competent to deal with the subject.

Your Committee hold that this inquiry is of a character sufficiently important to the nation, and sufficiently wide in its scope, to demand the most ample and most powerful machinery that can be brought to bear upon it.

Your Committee therefore submit, as the substance of their Report, the recommendation that the full influence of the British Association for the advancement of Science should at once be exerted to obtain the appointment of a Royal Commission, to consider:—

1. The character and value of existing institutions and facilities for scientific investigation, and the amount of time and money devoted to such purposes.
2. What modifications or augmentations of the means and facilities that are at present available for the maintenance and extension of science are requisite; and,
3. In what manner these can be best supplied.

To proceed with our historical narrative. The report passed through the ordeal to which all such matters are subjected according to the rules of the British Association; namely, First, the consideration of the committee of the Section in which it originated (Section A); Secondly, that of the Committee of Recommendations; Thirdly, that of the General Committee. By this last it was submitted to the Council of the Association, "*for consideration and action if it seems desirable*," and the report was considered by a sub-committee of the Council on Saturday last.

As the matter now stands, it is for the Council of the British Association to determine whether science in this country stands, or does not stand, on a settled, satisfactory foundation; and if not, then the further question, whether anything short of an inquiry conducted by the State will suffice to redress existing evils and to initiate desirable reforms.

If we refer to the list of names of the Norwich Committee, given above, we find that it includes men of the highest eminence in almost every branch of scientific inquiry,—men whose whole lives are, and have long been, devoted to actual scientific work—professors, investigators, and writers, members of many learned societies, and of universities, leaders of philosophical thought, and persons possessing every available means of insight into all that passes in the scientific world,—and what do they tell us? Why, virtually this, that the provision for extending science in England is derived from so many sources, is subject to so many authorities, is so entirely without consistency and system, that even their joint knowledge fails to grasp and arrange the heterogeneous mass of confusion; they say, however, with an absence of circumlocution that bears the stamp of well-founded conviction, that this

* The following names have since been added to the Committee:—Alfred Tennyson, F.R.S.; Lyon Playfair, F.R.S., M.P.; J. Norman Lockyer, F.R.S.

provision, such as it is, not merely fails as to system and quality, but that, as to extent and quantity, "*it is far from sufficient for the vigorous prosecution of Physical Research.*"

Now, the opinions of men like these, so clearly and strongly expressed, must have carried great weight, whatever recommendations they might have founded on them; but when we consider their recommendation our faith in the soundness of their advice receives a strong accession. They do not say, as they might have done,—Establish such institutions, abolish others, alter the constitution of some, create great scientific offices, elevate the condition of scientific men, form us into a body for setting everything to rights, ourselves included. No; with an impartiality that does them honour, they say,—Place this matter before the highest tribunal known to our constitution for the deciding of such questions—before men selected for their high station and unquestionable independence; let all branches of science come in succession under their scrutiny; let the truth appear openly before the world without a possibility that an imputation of partiality and favouritism, which might attach to *our* decision, should cast a shade over their proceedings and their judgment and so damage the cause.

If we next consider the composition of the Council of the British Association, we shall feel the most positive assurance that a Report coming to them from so strong a Committee will be considered with the utmost care. For our own part we cannot feel doubtful of the result. But the question whether or not the Government shall be asked for a Royal Commission on Science is at this moment in their hands, and having said this we have brought down the history of the movement to the present moment.

A few words in conclusion. This is precisely one of those subjects which is liable to be dealt with in detail by minds before which it is definitely presented for the first time. Let us, therefore, indicate briefly the main questions, the discussion of which is, in the present stage of the matter, desirable. These are: First, does scientific investigation labour in England under disabilities and disadvantanges for want of the necessary funds and material appliances? Secondly, on what principles should the State assist scientific exertion; are these principles settled and acknowledged; and are they acted on? Thirdly, if the answers to these questions be, as we may almost assume they will be, unfavourable, is there any chance that piecemeal rectification will suffice to correct existing evils, or must we go to the root of the matter with the help of a Royal Commission?

When these questions are settled, it will be time to go more into details—but not before.

PHYSICAL METEOROLOGY

II.—SUGGESTIONS

AT the end of a previous article, I ventured to say I should make some suggestions touching a method by which I think meteorology might perhaps be made a branch of physical inquiry. In doing so, I will borrow the thought, and very many of the words which were brought before the Exeter meeting of the British Association. And furthermore, no allusion will be made in the present article to the elements of pressure and temperature.

With respect to the motion of our atmosphere, it cannot be anticipated that we shall ever possess the same complete knowledge which astronomy gives us of the motion of the heavenly bodies; for in the latter case the identity of the object is not lost sight of, while in the former case it is clearly impossible to ascertain the motions of individual particles of air. Our inquiries into the distribution and motion of the elements of our atmosphere must, therefore, be pursued by that method which enables us to ascertain the distribution and motion of any other substance or product with the individual components of which we find it impracticable to deal.

Suppose, for instance, we wish to ascertain the wealth of our country in grain or in spirits, and the distribution of this commodity over the earth's surface. We should first of all begin by taking the stock of the commodity corresponding to a given date; we should next keep a strict account of all the imports and exports of the material, as well as of its home production and home consumption.

Now, if we have taken stock properly at first, and if our account of the imports, the exports, the production, and the consumption of our material is accurate and properly kept, it will obviously be unnecessary to take stock a second time. But if these accounts are not kept with sufficient accuracy, or if we suspect that our material leaves us by some secret channel which we wish to trace, it will clearly be necessary to take stock frequently; and thus a comparison of our various accounts may enable us to detect the place and circumstances of that secret transit which has hitherto escaped our observation.

Applying these principles to the vapour of our atmosphere, what we wish to know is the amount of this material present at any one station at any moment, and also the laws of its motion. It would appear that the best way of measuring the amount present at any moment is by ascertaining the *mass* of vapour present in a *cubic foot* of air, mass and volume being fundamental physical conceptions.

Next, with regard to the motion of the atmosphere, including its vaporous constituent, the method of co-ordinates suggested by Dr. Robinson would appear to be the natural way of arriving at this. Let us set up at a station two imaginary apertures (strictly imaginary, of course), one facing north and south and the other east and west, and gauge the mass of dry air and the mass of moisture that passes each of these openings in one hour; we shall by this means get the nearest attainable approach to the elements of motion of the atmospheric constituents from hour to hour. We shall not, however, obtain by this means a complete account of this motion, for we have at present no means of measuring its vertical component. This vertical component corresponds in fact to the secret channel in the illustration given above, which we must endeavour to detect by some indirect method. Another thing that ought to be determined is the production or consumption of the vaporous element of our atmosphere as it passes from place to place. This might be done could we keep an accurate account of the evaporation and the precipitation, the two processes by which this element is recruited and consumed. This would, however, be a very difficult observation.

Let us now recapitulate what information regarding moisture we can obtain from such complete meteorological observations as are at present made. We have to begin with, as I have shown—

(1) The mass of vapour actually present at a station from hour to hour.

(2) The mass that passes a station in one hour, going east and west.

(3) The mass that passes a station in one hour, going north and south.

There is wanting—

(4) The vertical component of the motion of vapour.

(5) Its production or consumption as it passes from place to place.

These deficiencies may, however, be to some extent overcome by the following considerations:—

First, the atmosphere moves as a whole when it moves, the dry and moist air moving together; *secondly*, dry air is neither capable of production nor of consumption, but always remains constant in amount.

To illustrate this part of the subject, let it be supposed that we wish to investigate the vertical motion of the atmosphere at a certain station. Make this station the imaginary centre of a circle, the circumference of which may be supposed to be studded with other stations at sufficiently frequent intervals, so that we can tell, hour by hour, how much dry air passes in towards the centre of the circle through its circumference, and also how much passes out.

Let us suppose that more is passing in than is passing out, or that the imports into the area of the circle are greater than the exports out of it. Now, the dry air that passes in is incapable of production or of consumption, and hence the stock of the material at the central station, and in the area generally, ought to be on the increase, since we have imagined the imports to be greater than the exports. If, however, we ascertain from actual observation that the stock of dry air is diminishing instead of increasing, we may be sure that some is carried off by an upward current, which of course carries the moisture with the dry air.

The establishment of accurate observations is so recent that I cannot at this moment produce any definite example in illustration of this mode of analysis. We may, however, take a cyclone. As I have said, there are two hypotheses with regard to the motion of air in this phenomenon: one set of philosophers advocating a strictly rotatory motion, and the other set an indraught of air from the circumference towards the centre; and yet frequently we have a falling barometer in the centre. Now, what can carry off the air, if there be not an ascending current at the very heart of the cyclone? This is, however, I may remark, merely put forward in illustration of the method.

So much for the vertical component; and now, in the next place, with regard to the production or consumption of aqueous vapour as it passes from place to place. Our consideration has hitherto been confined to *quantity*; let me now define what is meant by the *hygrometric quality* of the air. It may be represented by the following quotient:—

$$\frac{\text{mass of vapour in a cubic foot}}{\text{mass of dry air in a cubic foot}}.$$

Now, this quotient can only alter by evaporation, by precipitation, or by mixture. This hygrometric quality of the air may perhaps be considered a quality sufficiently constant to aid us in tracing the actual motion of air, just as we may make use of the element of saltness to trace the actual path of an oceanic current. It gives us, in fact, a chemical analysis of the air, and one, moreover, which is independent of pressure, so that we can tell by its means the various qualities of air which we meet with in a balloon or mountain ascent. But besides this aid, we may make use of it to enable us to tell the precipitation or evaporation. For instance, a very damp air, in passing over a very dry country, may be supposed to emerge less damp, having its hygrometric quality changed; or a very dry air, in passing over a very damp country, may be supposed to emerge less dry, having its quality changed in the opposite direction. Thus, by actual observation of the quality of the air at the time of its reaching some particular tract of land or ocean, and at the time of its leaving it, we may possibly get much better observations of what goes on in the country, as far as this particular research is concerned, than if it were studded with gauges.

I would therefore suggest that meteorological observations should, by a system of reduction, be made to show—

(1) The mass of dry air and of moisture in one cubic foot actually present at each station from hour to hour.

(2) The mass of dry air and of moisture that passes each station, hour by hour, in two lines of direction at right angles to each other, namely, north and south and east and west.

When these hourly elements are obtained, they might for seasonal changes be reduced after the method of five-day means; or for the investigation of changes of weather, they might be utilised in some other way, as, for instance, in that lately suggested by the Astronomer Royal.

I ought to remark of this method of *gauging*, that all I claim to have done is to have put it in a somewhat new form; for it has been acted on by Maury and others before now, and has, in fact, given us one proof of the anti-trades. For we know that there is a constant indraught of air from the tropics to the equator on both sides; and as it does not accumulate there it must be carried off somehow, that is to say, it must return by the upper regions.

Before concluding,—one word of recapitulation as to the present stage of development of meteorology. We have seen that, judging by astronomy, there ought to be three stages: the object of the first being to ascertain the actual motions of the air, the second the causes of those motions, while we prophesy in the third. We have also seen how little progress we have made in the very first of these; and we may naturally conjecture that the third or prophetical stage is so very far in advance of us that we may not reach it for a long time. Nevertheless there is one crumb of comfort for weather prognosticators; for just as astronomers predicted certain phenomena in a rough way before the law of gravitation was established, so here also we may make certain rough and ready predictions of much practical utility before the advent of the Newton of meteorology.

BALFOUR STEWART

SERMONS IN STONES

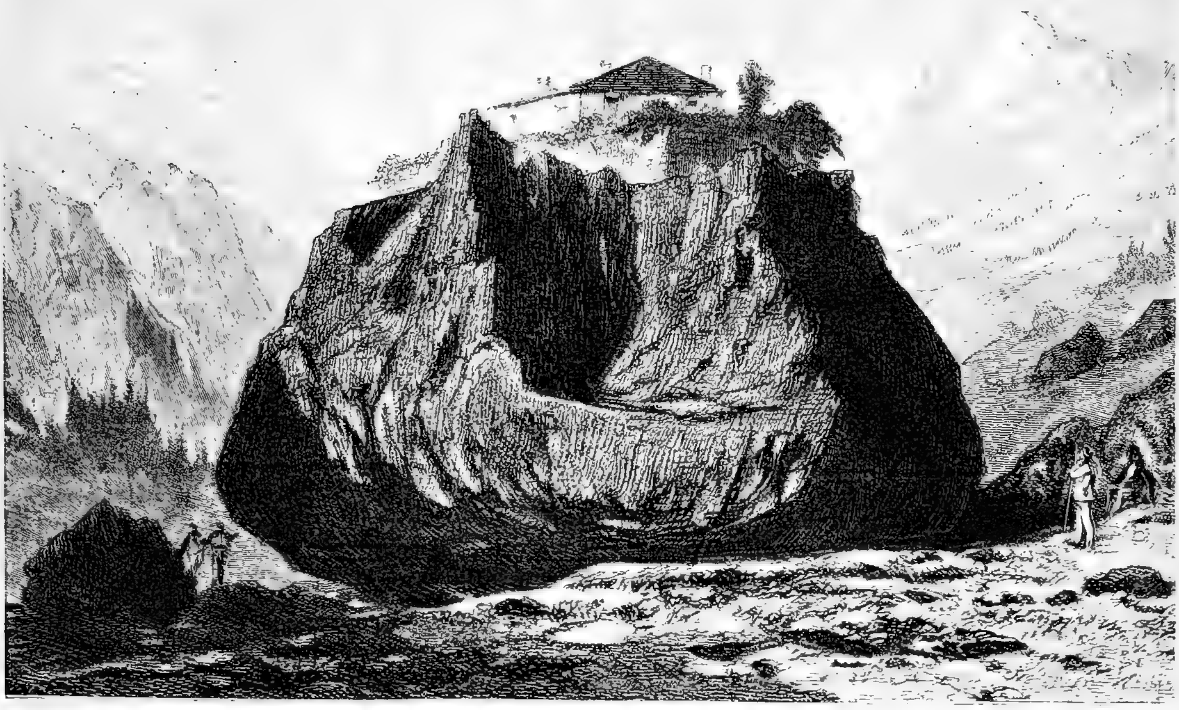
Les Pierres, Esquisses Minéralogiques. Par L. Simonin. Pp. 516, with 91 woodcuts, and 21 chromo-lithographs for coloured plates. (Paris, 1869. Hatchette et Cie.)

THIS volume is another of the recent works on popular science which, like "La Vie Souterraine" of the same author, "Les Volcans" of Boscowitz, and others of a similar character, the publishers of Paris seem of late to compete with one another in bringing out, and of which it may be said that they are peculiarly French, for neither here, elsewhere on the Continent, nor in England do we find their exact representatives.

Copiously illustrated by chromo-lithographs, coloured plates, and woodcuts of a most spirited, and occasionally what may be termed a somewhat sensational, character, these works apparently seek to impart scientific information mainly by appealing to the eye of the reader, and it must be admitted that in this they are sometimes very successful, the illustrations often conveying at a glance impressions which it would be tedious, or at times even difficult, to communicate in words. As an example of this, and also at the same time of the style of the woodcuts themselves, which are so abundant in the volume now under consideration, we reproduce two of them in our pages. The first of these is a most successful attempt to depict the general features of one of those polar glaciers which in prehistoric times have played so important a part in the earth's geological history, by the transporting of vast accumulations of rocks and their *débris* to other parts of the globe far distant from their original sites. This woodcut may be said to be, as it were, supplemented by the second, representing a Swiss landscape, showing in the foreground one of the great erratic blocks, or boulders, carried far from the glaciers themselves, and deposited in its present situation upon the melting of the icy raft which had floated it southwards. It may fairly be asked whether any description would be likely to produce on the mind of the geologically-inclined reader the effect which the mere sight of this woodcut must do? Does not the appearance of this gigantic pebble, with the dwelling-house perched upon its summit, instantly convey the most vivid impression of the more than grand scale of those glacial phenomena which at one period of the earth's history exhibited themselves in full activity?

POLAR GLACIERS

Bearing in mind that the word "stone" is throughout this work employed in an altogether popular sense—*i.e.* used promiscuously to designate any fossil, loose stone, rock, or mineral species whatsoever—the book itself is divided into two parts, treating respectively—(1) of stones, as a group or family, and (2) of the history of certain stones. Under the former of these heads, after a somewhat vague introduction to mineralogy proper, and a more detailed description of the somewhat complicated and cumbrous equipment considered by the author as necessary for the travelling mineralogist, or rather geologist, we find, in the second chapter, what might be called the condensed essence of geological science. Starting with cosmogony, we have laid before us, in turn, the nebular hypothesis of the origin of the earth; its subsequent condition of igneous fluidity, and consolidation upon cooling; the appearance of life upon its surface; and the various subsequent changes which it experienced through successive geological ages down to the present day,—the text being but a sort of running commentary upon the numerous and often admirably-executed illustrations which occur in its pages.



PIERRE DES MARMETTES, AT MONTHEY (VALAIS)

From this we are, in the third chapter, carried to the consideration of what are termed the stones of France; under which head we find a hurried but interesting account of the coal and iron mines of France, and of the utilisation of their products in the metallurgical industries of the country, interspersed with sketches of their history, statistics, &c., of the mining and manufacturing population; concluding with a still shorter account of the other more strictly denominated metallic mines of France.

A fourth chapter completes this first division of the work by a description of what are termed "Les Pierres du Globe," arranged under the heads of—(1) Carbon, (2) Metallic substances, (3) Building stones, (4) Gems, (5) Earths and salts, (6) Petroleum and subterranean water; all of which are treated of in a very interesting, but necessarily, from want of space, equally superficial manner.

The second part of the work, or what is termed the "Histoire de quelques Pierres," is subdivided into four chapters, each of which is in itself a somewhat more detailed account of the mining industry carried on in certain districts more specially noted for their mineral productions. These are as follows:—(1) The gold and silver deposits of the Rocky Mountains; (2) The marble quarries of Italy; (3) The iron mines of Elba; and (4) The coal mines of the centre of France. The descriptions of these are given in a very characteristic and instructive manner, and here again we may remark that they are profusely illustrated.

In reviewing this book, it must be remembered that Simonin's "Les Pierres" is not to be regarded in the light of a strictly scientific work, nor is it put forward with any pretensions to such a character. Although treating of subjects within the domain of their respective sciences, it is evidently, and admittedly, *not* written for the use of either mineralogist, geologist, or metallurgist; it claims but to provide those readers who are not at home in mineralogical or geological science, with information, arranged in a popular, or, to them, readable form, concerning such mineral substances as are likely to come under their attention either at home or in the course of their travels, and as such we cannot but recommend it.

The worthlessness of coloured illustrations of minerals has frequently been descanted upon, and it is perfectly true that they can be of no utility whatsoever to the student in mineralogy; in the present instance, however, they may be looked upon as but so many ornaments contributing to the general attractiveness of the volume as a whole. We are inclined to the belief that publications of this character, without being profound, or even free from some not inconsiderable defects, may still do good service to the cause of science, by attracting the attention of readers who, misled by vulgar report, eschew, without trial, what is commonly called the usual dry scientific literature; and that in some instances at least it may induce them to follow up their introduction by the study of more substantial scientific pabulum.

DAVID FORBES

THE ORIGIN OF SPECIES CONTROVERSY

Habit and Intelligence, in their Connection with the Laws of Matter and Force. A Series of Scientific Essays. By Joseph John Murphy. (Macmillan and Co., 1869.)

II.

IN his chapter on "The Rate of Variation," Mr. Murphy adopts the view (rejected after careful examination by Darwin) that in many cases species have been formed at once by considerable variations, sometimes amounting to the formation of distinct genera and he brings forward the cases of the Ancon sheep, and of remarkable forms of poppy and of *Datura tatula* appearing suddenly, and being readily propagated. He thinks this view necessary to get over the difficulty of the slow rate of change by natural selection among minute spontaneous variations; by which process such an enormous time would be required for the development of all the forms of life, as is inconsistent with the period during which the earth can have been habitable. But to get over a difficulty it will not do to introduce an untenable hypothesis; and this one of the rapid formation of species by single variations can be shown to be untenable, by arguments which Mr. Murphy will admit to be valid. The first is, that none of these considerable variations can possibly survive in nature, and so form new species, unless they are *useful* to the species. Now, such large variations are admittedly very rare compared with ordinary spontaneous variability, and as they have usually a character of "monstrosity" about them, the chances are very great against any particular variation being useful. Another consideration pointing in the same direction is, that as a species only exists in virtue of its being tolerably well adapted to its environment, and as that environment only changes *slowly*, small rather than large changes are what are required to keep up the adaptation. But even if great changes of conditions may sometimes occur rapidly, as by the irruption of some new enemy, or by a few feet of subsidence causing a low plain to become flooded, what are the chances that among the many thousands of *possible* large variations the one exactly adapted to meet the changed conditions should occur at the right time? To meet a change of conditions this year, the right large variation *might* possibly occur a thousand years hence.

The second argument is a still stronger one. Mr. Murphy fully adopts Mr. Herbert Spencer's view, that a variation, however slight, absolutely requires, to ensure its permanence, a number of concomitant variations, which can only be produced by the slow process of self-adaptation; and he uses this argument as conclusive against the formation of complex organs by natural selection in all cases where there is no tendency for action to produce self-adaptation; *à fortiori*, therefore, must a sudden large variation in any one part require numerous concomitant variations; it is still more improbable that they can accidentally occur together; it is impossible that the slow process of self-adaptation can produce them in time to be of any use; so that we are driven to the conclusion, that any large single variation, unsupported as it must be by the necessary concomitant variations, can hardly be other than hurtful to the individuals in which it occurs, and thus lead in a state of nature to its almost immediate extinction. The question, therefore, is not, as Mr. Murphy seems to think, whether such large variations occur in a state of nature, but whether, having occurred, they could possibly maintain themselves and increase. A calculation is made by which the more rapid mode of variation is shown to be necessary. It is supposed that the greyhound has been changed from its wolf-like ancestor in 500 years; but it is argued that variation is much slower under nature than under domestication, so that with wild animals it would take ten times as long for the same amount of variation to occur. It is also said that there is ten times less chance of favourable variations being preserved, owing to the free intermixture that takes place in a wild state; so that for nature to produce a greyhound from a wolf would have required 50,000 years. Sir W. Thomson calculates that life on the earth must be limited to some such period as one hundred million years, so that only two thousand times the time required to produce a well-marked specific change has, on this theory, produced all the change from the protozoon to the elephant and man.

Although many of the data used in the above calculation are quite incorrect, the result is probably not far from the truth; for it is curious that the most recent geological researches point to a somewhat similar period as that required to change the specific form of mammalia. The question of geological time is, however, so large and important that we must leave it for a separate article.

The second volume of Mr. Murphy's work is almost wholly psychological, and can be but briefly noticed. It consists to a great extent of a summary of the teachings of Bain, Mill, Spencer, and Carpenter, combined with much freshness of thought and often submitted to acute criticism. The special novelty in the work is the theory as to the "intelligence" manifested in organisation and mental phenomena, and this is so difficult a conception that it must be presented in the author's own words :—

"I believe the unconscious intelligence that directs the formation of the bodily structures is the same intelligence that becomes conscious in the mind. The two are generally believed to be fundamentally distinct: conscious mental intelligence is believed to be human, and formative intelligence is believed to be Divine. This view, making the two to be totally unlike, leaves no room for the middle region of instinct; and hence the marvellous character with which instinct is generally invested. But if we admit that all the intelligence manifested in the organic creation is fundamentally the same, it will appear natural, and what might be expected, that there should be such a gradation as we actually find, from perfectly unconscious to perfectly conscious intelligence; the intermediate region being occupied by intelligent though unconscious motor actions—in a word, by instinct. . . . . The intelligence which forms the lenses of the eye is the same intelligence which in the mind of man understands the theory of the lens; the intelligence that hollows out the bones and the wing-feathers of the bird, in order to combine lightness with strength, and places the feathery fringes where they are needed, is the same intelligence which in the mind of the engineer has devised the construction of iron pillars hollowed out like those bones and feathers. . . . . It will probably be said that this identification of formative, instinctive, and mental intelligence is Pantheistic. . . . . I am not a Pantheist: on the contrary, I believe in a Divine Power and Wisdom, infinitely transcending all manifestations of power and intelligence that are or can be known to us in our present state of being. . . . . Energy or force is an effect of Divine power; but there is not a fresh exercise of Divine power whenever a stone falls or a fire burns. So with intelligence. All intelligence is a result of Divine Wisdom, but there is not a fresh determination of Divine thought needed for every new adaptation in organic structure, or for every new thought in the brain of man. Every Theist will admit that there is not a fresh act of creation when a new living individual is born. I go a little further, and say that I do not believe in a fresh act of creation for a new species. I believe that the Creator has not separately organised every structure, but has endowed vitalised matter with intelligence, under the guidance of which it organised itself; and I think there is no more Pantheism in this than in believing that the Creator does not separately cause every stone to fall and every fire to burn, but has endowed matter with energy, and has given energy the power of transposing itself."

I am not myself able to conceive this impersonal and unconscious intelligence coming in exactly when required to direct the forces of matter to special ends, and it is certainly quite incapable of demonstration. On the other hand, the theory that there are various grades of conscious and personal intelligences at work in nature, guiding the forces of matter and mind for their purposes as man guides them for his, is both easily conceivable and is not necessarily incapable of proof. If therefore there are in nature phenomena which, as Mr. Murphy believes, the laws of matter and of life will not suffice to explain, would it not be better to adopt the simpler and more conceivable solution, till further evidence can be obtained?

The only other portion of the work on which my space will allow me to touch, is the chapter on the Classification of the Sciences, in which a scheme is propounded of great simplicity and merit. Mr. Murphy does not appear to be acquainted with Mr. Herbert Spencer's essay on this subject, and it is somewhat remarkable that he has arrived at so very similar a result, although less ideal and less exhaustively worked out. In one point his plan seems an improvement on all preceding ones. He arranges the sciences in two series, which we may term primary and secondary. A primary science is one which treats of a definite group of *natural laws*, and these are capable of being arranged (as Comte proposed) in a regular series, each one being more or less dependent on those which precede it, while it is altogether independent of those which follow it. A secondary science, on the other hand, is one which treats of a group of *natural phenomena*, and makes use of the primary sciences to explain those phenomena; and these can also be arranged in a series of decreasing generality and independence of those which follow them, although the series is less complete and symmetrical than in the case of the primary sciences. The two series somewhat condensed are :—

Primary Series.	Secondary Series.
1. Logic.	1. Astronomy.
2. Mathematics.	2. Terrestial Magnetism.
3. Dynamics.	3. Meteorology.
4. Sound, Heat, Electricity, &c.	4. Geography.
5. Chemistry.	5. Geology.
6. Physiology.	6. Mineralogy.
7. Psychology.	7. Palæontology.
8. Sociology.	8. Descriptive Biology.

Taking the first in the list of secondary or compound sciences, Astronomy, we may define it as the application of the first five primary sciences to acquiring a knowledge of the heavenly bodies, and we can hardly say that any one of these sciences is more essential to it than any other. We are, perhaps, too apt to consider, as Comte did, that the application of the higher mathematics through the law of gravitation to the calculation of the planetary motions, is so much the essential feature of modern astronomy as to render every other part of it comparatively insignificant. It will be well, therefore, to consider for a moment what would be the position of the science at this day had the law of gravitation remained still undiscovered. Our vastly multiplied observations and delicate instruments would have enabled us to determine so many empirical laws of planetary motion and their secular variations, that the positions of all the planets and their satellites would have been calculable for a moderate period in advance, and with very considerable accuracy. All the great facts of size and distance in planetary and stellar astronomy, would be determined with great precision. All the knowledge derived from our modern telescopes, and from spectrum analysis, would be just as complete as it is now. Neptune, it is true, would not have been discovered except by chance; the nautical almanack would not be published four years in advance ; longitude would not be determined by lunar distances, and we should not have that sense of mental power which we derive from the knowledge of Newton's grand law ;—but all the marvels of the nebulæ, of solar, lunar, and planetary structure, of the results of spectrum analysis, of the velocity of light, and of the vast dimensions of planetary and stellar spaces, would be as completely known to us as they now are, and would form a science of astronomy hardly inferior in dignity, grandeur, and intense interest, to that which we now possess.

Mr. Murphy guards us against supposing that the series of sciences he has sketched out includes all that is capable of being known by man. He professes to have kept himself in this work to what may be called positive science, but he believes equally in metaphysics and in theology, and proposes to treat of their relation to positive science in a separate work, which from the author's great originality and thoughtfulness will no doubt be well worthy of perusal.

ALFRED R. WALLACE

OUR BOOK SHELF

Nature contemplated Philosophically.—*Die Natur im Lichte philosophischer Anschauung.* By Maximilian Perth. (Leipzig and Heidelberg, 1869.) Large 8vo. pp. viii. and 805.

THE modern developments of the study of natural science have led to the separate and too exclusive consideration of branches of knowledge. This result necessarily follows from the defects inherent in our methods of investigation; but everyone will admit the importance and advantage of contemplating Nature as a whole, instead of attending to a fragment of her works. Hence she must be contemplated philosophically; for it is the business of philosophy alone to work out the greater problems which are common to, and underlie, the great problems of the sciences.

Such are the views which led Prof. Perth to write this book, a task for which he had fitted himself by many-sided study from boyhood, and the accomplishment of which has exacted the labour of several years. It is a purely philosophic work, belonging to a class of which there are few specimens, and cannot be easily read except by those who have some technical acquaintance with philosophic terms. The following are titles of a few of the topics treated in the volume:—"Matter, Organism, Spirit;" "The Relation of Nature to the Moral Idea;" "The Chemical Process;" "Species;" "The Chronological Perfection of Organic Nature;" "The Geographical Distribution of Plants;" "The Spiritual Life."

The author does not attach himself to any particular school of thought; but Kant, Hegel, and Spinosa have, perhaps, a predominance. His information is universal; but the erudition displayed is accompanied, as generally happens, by a want of point, precision, and climax. Here and there, a somewhat sad and sombre eloquence relieves and ornaments the picture. E. J. M.

An Introduction to the Science of Heat.—By Temple Augustus Orme. (London: Groombridge & Sons.)

IT is not many years since the appearance of the first thoroughly scientific treatise on heat in the English language, and now we hail the advent of a well-written introduction to more advanced works: a book intended for the beginner who is supposed to possess nothing but a fair knowledge of arithmetic and an average amount of intelligence. This book is full of excellent examples of the various laws of heat, in which the author makes use of the metrical system of measurements, and the centigrade scale of temperature; and the student who has worked through these questions cannot fail to have acquired a good practical knowledge of the subject of heat, as well as an appreciation of the advantage of the metrical system. Nor are theoretical views left out, and although the treatise only professes to be an introductory one, we have a good elementary account of the dynamical theory of heat, including the grand laws of the conservation and dissipation of energy. The author is undoubtedly right in accustoming the student at an early age to think of, and if possible apprehend, this great generalisation, for in truth it forms the appropriate supplement to and completion of the ordinary laws of motion, and should be studied along with these; otherwise the student may be led to conceive that when two equally massive inelastic balls strike one another with equal and opposite velocities, the result is *nil*, and to entertain many similar absurdities. And inasmuch as the laws of motion find their way into introductory treatises on natural philosophy, so should the laws of energy find a place in these. In the study of such laws, the student cannot too soon become accustomed to those technical terms which are necessary to give accurate expression to his conception; and we are glad the author has introduced the terms *kinetic* and *potential*, although we think that on one or two occasions he has used the word *force* where *energy* would have been preferable.

B. S.

Sicilian Fungi.—*Funghi Siciliani.* Per Guiseppe Inzenga. Centuria Prima. 4to. pp. 95, with 8 coloured plates, price 10*s*. (Palermo, 1869. London: Williams and Norgate.)

A WORK which will be very welcome to English fungologists, and especially to those who are interested in fungophagy. We have here descriptions of 100 of the more conspicuous Fungi of Sicily, with coloured plates of some of the more important or newly-described species, an account of their localities, and of the uses to which they are applied; and, what is of no small importance in a work on Fungi, a list of the synonyms belonging to each species. Sig. Inzenga has paid special attention to the economic properties of the Sicilian Fungi; among this first century he enumerates 30 species, which he can vouch for as being perfectly wholesome, more or less delicate in flavour, and easily distinguished from any noxious species, many of them being largely used as articles of food by the Sicilian peasantry, and sold in the markets of Palermo and Messina; while only eight are named as being absolutely poisonous, or so suspicious as to be prudently rejected. Our common mushroom, which is forbidden to be sold in the markets of Rome, is freely eaten in Sicily, though not so much esteemed as several other species.

A. W. B.

The Microscope and its Applications.—*Das Mikroskop und seine Anwendung.* Von Dr. L. Dippel. Zweiter Theil. Anwendung des Mikroskopes auf die Histiologie der Gewächse. 8vo. pp. 328, with 188 woodcuts, and 6 lithographic plates, price 12*s*. (Brunswick, 1869. London: Williams and Norgate).

THE first part of Dr. Dippel's treatise on the microscope was devoted to a description of its different forms, with practical directions for its use and for the preparation of specimens; in the present volume we have an account of its application to the observation of the minute parts of plants. It is divided into four sections. The first consists of investigations of cells as distinct organisms, including the cell-membrane, the cell-nucleus, the cell-fluid, protoplasm, and salts; the formation of cells; and their transformation into tubes and vessels. The second part relates to the more complicated tissues of the higher cryptogamia and of the phanerogamia. The third records the results of investigations on the elementary organs and tissues in polarised light. The fourth part is occupied by an account of the anatomical structure or comparative anatomy of the different compound organs, the stem, root, leaves, and organs of reproduction. With this volume the work closes for the present, but an additional one is promised at some future time on animal histiology. It contains a clear record of the present state of microscopical science as applied to the minute structures of the vegetable kingdom, free from those abstruse speculations which often fill so large a portion of continental works of this description. The illustrations, both wood-cuts and lithographs, are of the excellence to which we are accustomed in German scientific works, and to each section is appended a list of all the important works and papers already published on the subject. A. W. B.

The Physical Phenomena of Life.—*Les Phénomènes Physiques de la Vie.* Par J. Gavairet, &c. (Paris: Masson et Fils. London: Williams and Norgate.)

WE do not quite see why this little book should have been written. It is too technical to be useful as a popular volume; it is too diffuse, and yet too incomplete, to be a text-book; and it has neither the critical grasp nor the originality of an independent essay. There is a grand opening for some one to gather up all the recent advances in physiological physics, and weld them up together into a single book. When we took this volume in hand, we hoped to find something of the kind; but it really consists of little more than a straggling discourse on animal heat, and another on muscular contraction. M. F.

THE DEEP-SEA DREDGING EXPEDITION IN H.M.S. "PORCUPINE"

I.—NATURAL HISTORY

My part of the expedition in H. M. S. *Porcupine* commenced on the 18th of May, and ended on the 13th of July last. It comprised the Atlantic coast of Ireland, from the Skelligs to Rockall (a distance of about 6½ degrees, or 400 miles), Loughs Swilly and Foyle on the north coast, and the North Channel on the way to Belfast. I took with me as assistant Mr. B. S. Dodd (who had accompanied me in former dredging expeditions); and as dredger Mr. W. Laughrin, of Polperro, an old coast-guardman, and an Associate of the Linnean Society. Both did their share of the work carefully and zealously.

The first dredging was on the 24th of May, about 40 miles off Valentia, in 110 fathoms; bottom sandy with a little mud. The fauna was mostly northern, and the following are the more remarkable species there procured: Mollusca—*Ostrea cochlear*, *Neæra rostrata*, *Verticordia abyssicola*, *Dentalium abyssorum*, *Aporrhaïs Serresianus*, *Buccinum Humphreysianum*, *Murex imbricatus*, *Pleurotoma carinata*, and *Cavolina trispinosa;* Echinodermata —*Echinus elegans*, *Cidaris papillata*, and *Spatangus Raschi;* Actinozoa—*Caryophyllia Smithii*, var. *borealis*. Of these, *Ostrea cochlear*, *Aporrhaïs Serresianus*, and *Murex imbricatus* are Mediterranean species; and *Trochus granulatus* also imparted somewhat of a southern character, although that species was afterwards found living in the Shetland district. *Ostrea cochlear* is a small Mediterranean species of oyster; and it is one of the shells which Milne-Edwards noticed as adhering to the telegraph-cable between Sardinia and Algiers from a depth of about 1,100 fathoms. Although considered peculiar to deep water, I found it attached to the columns of the temple of Jupiter Serapis at Pozzuoli, which are reputed not to have been submerged to any depth. The above-mentioned results of this dredging will give a fair idea of the fauna inhabiting the 100-fathom line on the west of Ireland.

After coaling at Galway we steamed south; and (the weather being very coarse and unpromising) we dredged in Dingle Bay, at a depth of from 30 to 40 fathoms; bottom rocky and muddy. As before, in comparatively shallow water, we had two dredges out, one at the bow, and the other at the stern; this was what I always did in my own yacht, when dredging in from 20 to 200 fathoms. In Dingle Bay the dredges several times caught in rocks or large stones, but were saved by the usual yarn-stops, and by the extraordinary strength of the two-inch Chatham rope which was used. On one occasion, when the dredge was fast, the steamer, which was nearly of 400 tons burden, was pulled round, and swung by the rope as firmly as if she were at anchor and moored by a chain cable. Here, again, the Mollusca were mostly northern. *Siphonodentalium Lofotense*, *Chiton Hanleyi*, *Tectura fulva*, *Odostomia clavula*, *Trophon truncatus*, and *Cylichna nitidula* fall within this category; and *Eulima subulata*, *Trophon muricatus*, *Pleurotoma attenuata*, and *Philine catena* may be reckoned southern species. But the most remarkable shell obtained in this dredging was *Montacuta Dawsoni*, which I had described and figured from specimens found by Mr. Robert Dawson in the Moray firth. I subsequently detected in the Royal Museum at Copenhagen specimens of the same species in the collection of Greenland shells, made by the late Dr. H. P. C. Möller. The species was briefly described or noticed by him in the addenda to his 'Index Molluscorum Groenlandiæ,' as "*Testa bivalvis*"*;* but he did not give it any other name. The size of the Greenland specimens is considerably greater than that of British specimens, thus adding another to the numerous cases of a similar kind which I have from time to time adduced in illustration of the fact, that with regard to those species of Mollusca which are common to northern and southern latitudes, and which inhabit the same bathymetrical zone, northern are usually larger than southern specimens. It may, perhaps, be a not unfair inference, that the origin of such species is northern, and that they dwindle or become depauperated, in proportion to the distance to which they have migrated, or been transported from their ancestral homes.

The following week was occupied in sounding and dredging off Valentia, and on the way to Galway, at depths varying from 85 to 808 fathoms. The fauna throughout was northern. Several interesting acquisitions were made in all departments of the Invertebrata. Among the Mollusca I may mention—*Nucula pumila* (Norway), *Leda frigida* (Spitzbergen and Finmark), *Verticordia abyssicola* (Finmark), *Siphonodentalium quinquangulare* (Norway and Mediterranean), and an undescribed species of *Fusus* allied to *F. Sabini;* Echinodermata—*Brisinga endecacnemos;* Actinozoa—*Ulocyathus* (or *Phyllodesmia*) *arcticus*. That fine sponge *Phakellia ventilabrum* was also met with so far south, in 90 fathoms. The 808 fathoms' dredging was then a novelty, being the greatest depth ever explored in that way. The length of rope paid out was 1,100 fathoms, and the time occupied in hauling in was 55 minutes. The same proportional time was observed in other dredgings during my part of the expedition, viz. 5 minutes for every 100 fathoms of rope. The dredge contained about 2 cwt. of soft and sticky mud, in appearance resembling "China clay." The animals brought up on this occasion were quite lively; and I examined more than one specimen of a small Gastropod (described and figured by me as *Lacuna tenella*), which had very conspicuous eyes: there was also an active little stalk-eyed crab.

The next cruise was for ten days, and comprised the examination of the sea-bed between Galway and the Porcupine Bank, as well as beyond the Bank, at depths varying from 85 to 1,230 fathoms. All the Mollusca were northern, except *Aporrhaïs Serresianus;* and even that I am now inclined to consider identical with *A. Macandreæ*, which inhabits the coasts of Norway and Shetland; the latter appears to be a dwarf variety or form. The more remarkable species were, *Limopsis aurita* (a well-known tertiary fossil), *Arca glacialis*, *Verticordia abyssicola*, *Dentalium abyssorum*, *Trochus cinereus*, *Fusus despectus*, *F. Islandicus*, *F. fenestratus*, and *Columbella haliæeti*, (a tertiary fossil), among the Mollusca; *Cidaris papillata* and *Echinus Norvegicus* among the Echinoderms, and the beautiful branching coral, *Lophohelia prolifera*. In the deepest dredging made in this cruise (1,230 fathoms), occurred several new species and two new genera of the *Arca* family, *Trochus minutissimus* of Mighels (a North American species) having two conspicuous eyes, a species of *Ampelisca* (Crustacea) with the usual number of four eyes, comparatively gigantic Foraminifera, and other animals belonging to undescribed species and genera. An enormous fish (*Mola nasus*), which is not uncommon on the coasts of upper Norway, was slowly swimming or floating on the surface of the sea; but we did not succeed in capturing it for want of a harpoon.

We then put into Killybegs, county Donegal, and coaled there for our Rockall cruise. In anticipation of this cruise taking a clear fortnight, coals were stacked on the deck, in addition to the usual stowage in the bunkers, so as to provide a sufficient supply. Some delay was caused by the non-arrival of a proper galvanometer to work Siemens' electro-thermometrical apparatus, which we were anxious again to try. We left Donegal Bay on the 27th of June, and returned to the mainland on the 9th of July, after experiencing severe weather. The vessel sustained some injury from the heavy cross seas which struck her on her homeward passage. During this cruise we dredged seven days at depths exceeding 1,200 fathoms, and on four other days at less depths; the greatest depth was 1,476 fathoms. In this last-mentioned dredging we got several living Mollusca and other animals, a stalk-eyed crustacean with two prominent and unusually large eyes, and an Echinoderm of the Holothuria family, of a blue colour. The bottom, at the greatest depths, consisted of a fine clayey mud, which varied in colour (in some dredgings being brownish, in others yellow, creamcolour, or drab, and occasionally greyish), and invariably having a greater or less admixture of pebbles, gravel, and sand. The upper layer formed a flocculent mass, which appeared to be animal matter in a state of partial decomposition. This was in all probability derived from the countless multitude of *Salpæ*, oceanic *Hydrozoa*, Pteropods, and other gelatinous animals, which literally covered the surface of the sea, and filled our towing net directly it was dipped overboard. Their remains must fall to the bottom after death. Such organisms doubtless afford a vast store of nutriment to the inhabitants of the deep. It must be borne in mind that it is extremely difficult to dredge in very deep water. The dredge must be unusually heavy to counterbalance the tendency of the necessary bulk of rope to buoy it up under the descending pressure; and when it reaches the bottom, it sinks by its own weight, like an anchor, into the mud. This would give only the same result as the cuplead or any sounding machine, but on a larger scale; and it would tell us very little about the fauna. Further, if by the drift-way of the vessel, or by a few turns of the engine now and then, we are enabled to scrape the surface of the sea-bed, the dredge gets choked up with the flocculent mass above described. The fertile ingenuity of our experienced and excellent commander devised a method which was a great improvement in deep-sea dredging, and which enabled us to obtain at least a sample of the substratum. This was to attach two iron weights, each of 100 lbs., to the rope, at a distance of 300 or 400 fathoms from the dredge (when the depth exceeded 1,200 fathoms), so as to dredge from the weights instead of from the ship, the angle thus made causing the blade of the dredge to lie in its proper position: in fact it reduced the depth by the distance of these weights from the vessel to the easy and manageable limit of 300 or 400 fathoms. Another method was to fasten the bag to the dredge in such a way that, when it was hauled in it could be unlaced, emptied, and afterwards washed quite clean. I was thus assured that the specimens really came from the place where each dredging was made, and the risk of intermixture with previous dredgings was avoided. My sieves were also framed with a similar object, every sieve having a beading round the inside rim, to prevent specimens remaining inside the edges when the sieves were washed after every dredging. Two other kinds of sieve I also found useful. One was spherical, with its lid fastened inside by bolts; its frame consisted of a strong network of copper ribs, which was lined with very fine gauze-wire of the same metal; and it had a ring through which a rope would pass. Its use was to sift and wash away in the sea the impalpable mud got in such quantities at great depths, so as to leave only for examination all organisms exceeding in size $\frac{1}{32}$ of an inch, this being the greatest diameter of the wire-mesh in the lining. Some of the residuum or strained mud was likewise preserved after sifting the material in the usual way. This apparatus, which we called the "globe-sieve," saved a great deal of the time and useless labour required for washing that sort of dredged material through the ordinary sieves in a tub of sea-water, which would immediately become so turbid that, unless the tub were continually emptied and refilled, it was extremely difficult (if not impossible) to detect any specimens. Another kind of sieve had a similar framework; but the body was semi-globose, with a funnel-shaped neck. It was fastened to a long pole, and served for catching Pteropods, *Salpæ*, and other animals on the surface of the sea. This went among us by the name of the "vase-sieve." We tried on this and other occasions a contrivance of Mr. Easton, the celebrated engineer, consisting of gutta percha valves, which closed inwards in a wedge-like form, and were fitted to the mouth of the dredge. The object was to retain the contents of the dredge while it was being hauled in, as I had found by frequent and disappointing experience that a large portion of the contents generally escaped through the mouth during this part of the operation. The contrivance, although admirable in a theoretical point of view, was found impracticable; perhaps it may yet succeed after more trials, and with some alterations. In their present form the valves close the mouth of the dredge, so that it has no contents to be retained. The deep-sea dredgings in this cruise yielded no end of novelties and interesting results in every department of the Invertebrata. They were enough to take one's breath away. Among the Mollusca were valves of an imperforate Brachiopod with a septum in the lower valve, which I propose to name *Cryptopora gnomon*. Some shells were of a tolerable size; and the fry of *Isocardia cor* (*Kelliella abyssicola* of Sars) were not uncommon. Many Crustacea (Amphipoda) were scarlet, and others bright red with feathered processes of a golden colour at the tail. A magnificent Annelid was pinkish, with purplish-brown spots on the line of segmentation. A *Holothuria*, from 1,443 fathoms, was 5 inches long and 2¼ in circumference. None of the animals, especially the Mollusca, were living when they were brought on board and examined; this was perhaps owing to the great change of temperature (sometimes as much as 20°) between that of the sea-bed and that of the atmosphere.

But to return from the bottom to the surface. At a distance of from 130 to 140 miles from the nearest part of the Irish coast I observed quantities of floating seaweed (mostly *Fucus serratus*) and feathers of sea-fowl, covered with *Lepas fascicularis*, and occasionally *L. sulcata;* and on the seaweed were also two kinds of sessile-eyed Crustacea. The wind having been previously easterly, it is difficult to say what share the wind or tide had in the drift; but it did not appear to have been caused by any circulation from the equator. The fauna nowhere showed the least trace of that wonderful and apparently restricted current known as the Gulf Stream. The beautiful Pteropod, *Clio pyramidata*, flitted about in considerable numbers; a delicate cuttle-fish (*Leachia ellipsoptera*), which is supposed to prey on *Salpæ*, was caught in the vase-sieve, as well as several specimens of a small and very slender pipe-fish or *Syngnathus*. One peculiar feature of this cruise was Rockall, an isolated and conical excrescence of the Atlantic, 70 feet high, and situate at least 200 miles from the nearest land. We lay to within a quarter of a mile of it on the evening of Saturday the 3rd of July, when fishing parties were formed, and continued their sport till midnight. The supply of fresh fish thus procured was very acceptable. The rock was inhabited by a multitude of sea-fowl; and a huge gannet perched on the highest pinnacle, looking like a sentinel, or the president of the feathered republic. On our return to Ireland, we dredged in Lough Swilly, Lough Foyle, and the North Channel, on the way to Belfast, where we arrived on the 13th of July. Here I parted with my shipmates and excellent companions, and enjoyed the hospitality and sympathy of my friends Professor Wyville Thomson and Mr. Waller.

After my part of the expedition was concluded, I went for the second time to Scandinavia, and compared notes with Dr. Koren at Bergen, Prof. Sars (now, alas! no more) at Christiania, Prof. Lovén at Stockholm, Prof. Lilljeborg at Upsala, Prof. Torell at Lund, Prof. Steenstrup and Dr. Mörch at Copenhagen, and with Prof. Möbius and Dr. Meyer at Kiel. All these zoologists had investigated the Mollusca in the Arctic and North-European seas; and the result of my interviews with them, and of examining the extensive collections in the public museums at the above places, was extremely useful in connection with the subject of the present report.

Prof. Wyville Thomson succeeded me on the 19th of July, and made a short but very successful cruise to the northern part of the Bay of Biscay, where he dredged at the extraordinary depth of 2,435 fathoms, or 14,610 feet. Some particulars of this dredging I have already given. Dr. Carpenter replaced Prof. Wyville Thomson on the 12th of August, and explored the sea-bed lying between the north of Scotland and the Faröe Isles. The depths there dredged did not exceed 650 fathoms; but the results are most interesting and important in a biological as well as physical point of view. Prof. Wyville Thomson accompanied Dr. Carpenter in the last part of the expedition. It terminated on the 7th of September.

J. GWYN JEFFREYS

(*To be continued.*)

UTILISATION OF SEWAGE

WE have been requested by the Secretary of the Committee * of the British Association on the Treatment and Utilisation of Sewage, to print the following letter, which has been sent to the Municipal Authorities throughout the country:—

22, Whitehall Place, London, S.W.
November 18th, 1869.

SIR,—I have the honour to inform you that, last year, at the meeting of the British Association at Norwich, a Committee was appointed to report on the Treatment and Utilisation of Sewage. In the first instance, a grant of £10 was placed at the disposal of the Committee, with which to defray the cost of printing and postage incidental to the collection of preliminary statistical information. Through the kindness of Her Majesty's Government, the Committee was enabled to obtain Reports respecting the methods of dealing with town refuse practised in most civilised countries, and that information has now been collected in a more complete form than hitherto existed in any country.

This preliminary work being completed, the Committee was re-appointed at the meeting of the British Association this year at Exeter, and the inquiry was considered to present such important features of social and scientific interest, that the sum of £50 was voted towards enabling the Committee to enter more fully and practically upon the investigation of this subject. The British Association being a purely scientific body, has not at its disposal funds which would be adequate or applicable for the full prosecution of this very large and pressingly-important inquiry. The Committee nevertheless desires to take advantage of the opportunity created by the British Association, to investigate the entire subject in all its bearings—whether chemical, physiological, or engineering, sanitary, municipal, or agricultural—and in a manner worthy of the body they represent.

It is unnecessary to point out the enormous importance, especially at the present time, of a full and complete investigation of this question by the light of the knowledge and experience now gained in the several departments above alluded to; but properly to carry out such an inquiry with a practical end, numerous observations, gaugings, and experiments, aided by simultaneous analyses, are essential; and these cannot be accomplished, especially the analyses, without the continued aid of efficient and therefore highly-paid assistants. Moreover, from time to time it may be necessary for the Committee to purchase extensive apparatus, and to subject various inventions and processes to a thorough and complete test; for it is the desire of the Committee, not only to ascertain, as far as possible, the causes of the sanitary inefficiency of existing works, but also to inquire into every suggestion which affords promise of practical utility, in order that this investigation may be searching, the report practical, and any recommendations that may be made authoritative.

It is the wish of the several members of the Committee to devote, to the utmost of their ability, their personal attention to the work thus sketched out; but the expenses absolutely necessary to enable them to conduct so extended an inquiry cannot but be very heavy, and, unless they are able to secure an adequate fund, they must abandon the attempt to investigate the subject in this broad and comprehensive manner. However, since there is no subject of greater practical and social importance to the public generally, and thus to the various municipal authorities and other governing bodies throughout the country, it is believed that many will share the opinion expressed at the recent meeting of the British Association at Exeter, that the existence of this Committee affords a specially favourable opportunity for such a wide inquiry, and for that reason its members confidently appeal to those authorities who are officially interested in the subject to supply the funds necessary for the investigation.

I am therefore desired to request that you will kindly submit this letter to the body you represent, and I venture to hope you will give the Committee the benefit of your good offices in procuring a subscription proportionate to the population of your town or district.

It is suggested that the subscriptions of towns of different populations might be graduated somewhat in the following proportions:—

Where the population does not exceed 10,000	£5	5	0
Between 10,000 and 25,000	10	10	0
Between 25,000 and 50,000	21	0	0
Between 50,000 and 75,000	30	0	0
Between 75,000 and 100,000	50	0	0
Above 100,000	100	0	0

I beg to call your attention to the accompanying list of members of the Committee, and to inform you that all public bodies subscribing not less than 5*l.* 5*s.* 0*d.* will have the benefit of the information from time to time, as the results of the inquiry partake of a conclusive character, and will receive a copy of the report of the Committee when published.

I have the honour to be, &c.,

GEORGE F. BARNES,
Honorary Secretary pro tem.

* The following are the names of the Committee:—Richard B. Grantham, Esq., M. Inst. C.E., F.G.S., Chairman; J. Bailey Denton, Esq., M. Inst. C.E., F.G.S.; J. Thornhill Harrison, Esq., M. Inst. C.E.; Benjamin H. Paul, Esq., Ph.D., F.C.S.; Profess Wanklyn, F.C.S.; William Hope, Esq. V.C.; Professor Williamson, Ph.D., F.R.S; Professor Marshall, F.R.S., F.R.C.S.; Professor Corfield, M.A., M.D.; M.C. Cooke, Esq.; and Sir John Lubbock, Bart., F.R.S., Treasurer. Subscriptions should be paid to the credit of Sir John Lubbock, on behalf of the Committee, at Messrs. Robarts, Lubbock, and Co.'s, 15, Lombard Street, London, E.C.

TELEGRAPHIC COMMUNICATION WITH FRANCE

LAST Tuesday, November 30, the S.S. *William Cory* left Greenhithe with a heavy submarine cable, to be laid between Salcombe in Great Britain and Cape Finisterre in France. This cable, 105 miles long, has just been made by the Telegraph Construction and Maintenance Company, at their works at North Woolwich, and its special object is to establish direct telegraphic communication between London and Brest, so as to expedite the transmission of messages between Great Britain and America by the French Atlantic Cable.

The new cable is very strong and heavy. The shore ends weigh 20 tons to the mile, and the deep-sea portion weighs very nearly 10 tons to the mile. It contains one conductor only, consisting of a strand composed of seven copper wires, and weighing, when twisted together, 107 pounds to the mile. The insulating medium is gutta-percha, and weighs 166 pounds to the mile. The contractors undertook that the electrical resistance of the conducting strand should not exceed 12·25 ohms per mile, and that the insulation resistance should not be less than 200 megohms (million ohms), at the standard temperature of 24 degrees centigrade. So well have the contractors done their work, that the quality of the cable is better than agreed upon, the conductivity resistance being only 11·8 ohms, and the insulation resistance nearly 400 instead of only 200 megohms per knot. The inductive capacity of this cable is as nearly as possible ·333 Farad. per mile.

The *William Cory*, since 1858, has laid many submarine cables; she carried and laid portions of the French Atlantic cables last summer, and is now employed solely in this new branch of industry. Captain Donaldson has been in charge of her throughout the whole of this period, and he took her out again last Tuesday, on which day she left Greenhithe for Salcombe. For the above details relating to the conductivity, insulation, and capacity of the cable, we are indebted to Mr. C. F. Varley, C.E., engineer to the French Atlantic Telegraph Company, who accompanies the expedition. The apparatus used in testing the cable was that described by his brother before Section A of the British Association at Exeter. By the time these lines are in print the cable may possibly have been laid, but much depends upon the weather. When the weather is fine, it usually takes half a day to lay each of the shore ends of a cable, and the deep-sea portion is ordinarily paid out at the rate of five knots per hour. The time occupied in paying out the deep-sea portion of the cable now under notice should be about twenty hours in all.

DR. PENNY, F.R.S.E.

IN our first number we had to record the death of Thomas Graham, one of the greatest chemists of the century, and formerly an occupant of the chair of chemistry in Anderson's Institution, Glasgow. We have now to announce the death of Frederick Penny, who, with the exception of the short interval between 1837 and 1839, when Gregory was its occupant, has filled it with increasing reputation and success ever since Graham vacated it to go to London, thirty-two years ago. Born in London in 1817, he was devoted to chemistry from his earliest years, and studied in the Apothecaries' Hall under Henry Hennell, F.R.S. It was while here that he was led to inquire into the combining weights of certain of the elements, by finding that the amount of potassic chloride obtained by acting upon pure potassic nitrate with excess of hydrochloric acid did not correspond with the quantity which theory showed should be obtained. Having made sure that the difference was not due to errors in his experiments, he ascribed it to inaccurate equivalents assigned to the elements. As the result of his investigations, he showed that the equivalents current at the time for chlorine, nitrogen, potassium, sodium, and silver were not in strict accordance with experiment, and that the "hypothesis of all equivalents being simple multiples of hydrogen is no longer tenable." [Phil. Trans. 1839. Part i. p. 32.] There can be no question as to the clearness of this paper and the value of the results obtained, and our interest in them is in no way diminished when we find that the equivalents determined by Penny agree in a very remarkable manner with the mean numbers published by Stas, and that this agreement has been pointed out by that chemist. [Fresenius, Zeits. für Annal. Chem. 1868, pp. 164, 168. Compare Penny's Table, Phil. Trans. 1839, i. p. 32, with Stas's Fres. Zeits. 1868, p. 170.]

The paper was published in January 1839, and the same year he was appointed to the vacant lecturership in Anderson's Institution. Dr. Penny himself has had but recently to give an account of his struggles and successes in Glasgow, since settling in it thirty years ago. Recommended by Graham, he went down to a sphere of life and action, more strange at that time to a native of London than it has since become; but he devoted himself strenuously to his work, and at the time of his death had won in Glasgow and the West of Scotland a wide reputation as one of the clearest and most emphatic lecturers, and one of the most painstaking teachers.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents.*]

Lectures to Working Men

I HEARTILY concur in Mr. Stuart's opinion, that the working men of England—speaking at least for the North—are fully aware of the value of Scientific Instruction in its strict sense. The subject has a special interest for me; as in the winter of 1866-7, I started in this city a series of Science Lectures for the People, which, with the kind help of Prof. Jevons, Dr. Alcock, and Dr. Morgan, were undertaken for the purpose of ascertaining whether the working men of Manchester really appreciate the value of science instruction when given in a plain, but scientific form, illustrated with diagrams and experiments made on a scale such as could be seen by a large audience. The experiment proved highly successful. Upwards of 4,000 people attended the thirteen Lectures which we gave, and the class of persons present was exactly that for whom the lectures were designed; whilst the marked attention and interest invariably exhibited by the audiences showed how keenly they appreciated the information they received, and the insight into true scientific methods which they obtained.

The lecturer's words were taken down by Mr. Pitman, and the lectures were each week printed and published by Mr. John Heywood, of Manchester, and largely sold at one penny each at the door of the lecture-room and elsewhere. I printed syllabuses of the chief points of my four lectures, and one was given to each person entering the room. When I say that the subject of my first lecture was the explanation of the principles of the Indestructibility of Matter and of Energy, with a description of Joule's Determination of the Mechanical Equivalent of Heat, I think you will see that mere amusement was not the aim; the same remark applies to all the other lectures, and yet I never met with a more attentive and appreciative audience than these Manchester working men.

Professor Jevons gave us a most excellent lecture on "Coal, its Value and Importance in the Arts and Sciences;" Dr. Alcock gave four capital lectures on Elementary Zoology, and Dr. Morgan a course of four on Elementary Physiology, a subject in which the greatest interest was evinced.

We charged one penny per head for admission, and the penny fees did not nearly cover the necessary outlay, which was defrayed by some friends. Not only was the expense a difficulty, but the work of carrying on such a system was more than could be regularly and gratuitously borne by men whose strength was already sufficiently taxed by their own professional duties. Otherwise the lectures would have certainly been continued, for we were all fully persuaded that no mode of commencing science teaching for the people is so effective as this, or so likely to ripen into a permanent demand for scientific education amongst the working classes. As a proof of this, I may add that for two winters a class was formed in connection with these lectures for regular instruction in Chemistry under an able Government science master—one of my pupils, who had gradually raised himself from the position of a common factory hand. For this instruction sixty working men each paid 2*s*. 6*d*. for thirteen lessons. I often looked in upon them, and a more hard-working and enthusiastic class I never had the good fortune to see.

If such science lectures, *followed up by regular science instruction*, could be permanently established every winter, under careful and thoroughly competent teachers, in each of our great centres of industry, what invaluable results might not be accomplished! This is truly a subject worthy of the attention of some of our wealthy philanthropists; if, indeed, Government does not take the matter up. How much better would it be to devote money to the establishment of such a series of science classes, than, as is too often the custom, to employ it for building an almshouse!

H. E. ROSCOE

Owens College, Manchester, Nov. 23, 1869.

Changes in Jupiter

DURING the months of October and November the planet Jupiter has presented a spectacle of singular and almost unexampled beauty. The belts on the planet are more than usually numerous, and they display a greater variety of colours than I have ever yet seen ascribed to them. The equatorial belt, which has been for years the brightest part of the planet, is now not nearly so bright as the light belts to the north and south; usually it has been free from markings, now it is often covered with markings, which resemble piled-up cumulus clouds: it has generally been colourless, shining with a silver-grey, or pearly lustre—now it is of a rich deep yellow, greatly resembling the colour of electrotyped gold.

The woodcut represents Jupiter as it was seen on the night of the 9th of March in a reflecting telescope with a silvered glass mirror of 12¼ inches diameter. The upper part of the planet is the S. pole. On this portion of the disc there are three dark belts, while on the N. there are only two.

The poles of the planet are ashy blue, and the darker belts nearest to them present a darker tint of the same colour. The bright belts next these are pearly-white, and shine more brilliantly than any other portion of the planet. The dark belts next to the central bright belts are coppery red. As already mentioned, the central belt, which has been for years a pearly-white, is now a rich golden yellow.

Three or four dark markings on the lower part of the southern dark belt nearest the equator will be seen to incline to the left. If our earth were removed to Jupiter's distance, its disc would appear no larger than these dark masses, so enormous is their extent. The rotation of the planet is carrying them towards the right: we may assume that the bright vapour between them is left behind by the planet, which is here travelling at the rate of nearly 3,000 miles an hour.

JUPITER, OCTOBER 9, 1869, 11 P.M. G M.T.

Spectrum analysis has taught us to suspect that any change in the colour of light proceeding from an object, indicates a change in the object itself. If Jupiter, the largest planet in the solar system, has still retained so much heat as to shine partially by his own light, the present considerable change in colour may enable spectroscopists to obtain some information on this interesting subject.

JOHN BROWNING

Cuckows' Eggs

WILL you kindly grant me space for a few remarks in reference to the very interesting paper on the eggs of the cuckoo, by Professor Newton, in your last issue? I have no intention to criticise so able and accomplished a naturalist: my object is simply to elicit information on some points of difficulty; and as Mr. Newton promises a second paper, I should be very glad if he would throw any light on them.

And first as to the colour and markings of cuckoos' eggs. *Are* they so variable as some assert? I must take leave to doubt this. I never met with such extreme varieties, nor can I hear amongst my oölogical friends of any who have done so. One of the most eminent and experienced of living oölogists has stated: "As far as my own experience goes, it teaches me that there are not many birds the eggs of which differ less than those of the cuckoo." On the other hand, Mr. Newton says: "It has long been notorious to oölogists, that the eggs of the cuckow are subject to very great variety of colour." This, then, is a point on which I think further evidence is wanting. Dr. Baldamus mentions sixteen varieties of eggs which he alleges are cuckoos'. Were these seen to be deposited by the bird, or how were they identified as those of the cuckoo? Dr. Baldamus does not appear to have taken them all himself. Is there not room for error here?

Mr. Newton saw these eggs, appears satisfied that they *were* those of the cuckoo, and agrees with Dr. Baldamus in his conclusions, that the object of the practice was that the cuckoo's egg should be "less easily recognised by the foster-parents as a substituted one." How then is this process effected? Mr. Newton's explanation is that each hen cuckoo deposits her eggs only in the nests of one species, that her eggs resemble those of the species whose nest she uses, and that this process is hereditary.

Here it is that I am most in doubt. How is this hereditary habit of laying a particular style of egg maintained? It is quite possible that habits may become hereditary; but is there any instance of a wild species of animal inhabiting one locality and freely intermingling, where some members possess peculiarities of habit which are hereditary which their fellows do not? Mr. Newton will excuse me for saying, that the Golden Eagle he mentions scarcely fulfils these conditions. Is it likely there are sixteen varieties of our common cuckoo which are only to be distinguished from each other by laying a differently marked and coloured egg? Few birds are more vagrant or possess less conjugal or parental affection than the cuckoo. How then are these sixteen varieties to be kept from crossing? And if, as I believe, interbreeding does take place, how can the alleged distinctive style of eggs be preserved? Here I am at fault, and I shall be very glad if Mr. Newton will help me out of my difficulty.

In the face of the alleged object that the egg shall be less easily recognised as a substituted one, how are we to account for the fact that, in this country at least, a larger number of cuckoos' eggs are deposited in the nests of the hedge sparrow than in those of any other species, the speckled brown egg contrasting *strongly* with the greenish blue ones?

W. J. STERLAND

The Corona

IN connexion with Mr. Lockyer's paper "On the Recent Total Eclipse of the Sun," the following observations may be useful.

I observed the total eclipse of July 1860, in company with my friends Professor Chevallier and Mr. B. E. Hammond, at the village of Pancorbo, in Spain. We were on the summit of a mountain of considerable height, about 5,000 feet above the sea, and were therefore under somewhat peculiar atmospheric conditions. I observed specially four things:—

(1) Venus; which was then extremely near the sun, the thickness of the crescent being only 1 or 2 seconds, and therefore very favourably placed for observing whether it has an atmosphere.

(2) The extent of the corona, and its form. This I am sure was very irregular; very nearly, if not quite, permanent during the three minutes of totality; was nowhere less than 25′ in breadth; in one part, the top in an inverting telescope, 40′ in breadth; and in another, the right, was more than 60′ in breadth, running out in a long wavy line like floss silk. I have before me the drawing I made at the time, during the totality.

(3) The amount of light given by the corona. This was estimated by a photometer, consisting of a wedge of dark glass, with a moveable slit, contrived by Mr. Chevallier, and now, I believe, in the possession of the Astronomical Society, with the place marked through which I saw the corona. It was as bright as a small cloud, distant 8° from the sun, 10 minutes after reappearance; or as the moon when 2½ days old, as the sun was setting.

(4) The colours shown by a variety of coloured ribbons during totality. Of these, the only observation that bears on Mr. Lockyer's paper, was that on the extent of the corona. I estimated it twice; once as reaching, to the right, 2¼ diameters of the sun, and once, later on, at nearly 2½ diameters. I had no micrometer, but could not possibly have been wrong by so much as 10′. I wrote down at the time, that it underwent no perceptible change during the eclipse. It remained visible for six seconds after the reappearance of the sun.

I had, and have, little doubt that the corona is in the solar, and not terrestrial atmosphere.

Rugby School, Nov. 11 JAMES M. WILSON

Lightning in a Clear Sky

WE constantly find allusions in ancient classical authors, to lightning and thunder occurring in a clear sky. The former is often explained as referring to the phenomenon commonly known as "summer lightning," or the reflection in the sky of lightning from clouds below the horizon, which becomes visible at night. I have also seen it stated that in the calm and clear atmosphere of Italy, thunder might be audible under similar conditions. These explanations, however, do not meet the case as stated by good observers amongst the ancients themselves. They do not explain, for instance, what is stated by Cicero amongst the portents which preceded the conspiracy of Catiline—"that a Roman citizen was killed by lightning on a cloudless day." Pliny also mentions this case, adding that it happened at Pompeii. If such a phenomenon as lightning, falling from a cloudless sky, is disbelieved by men of science, may not the circumstance stated above be explained by supposing the man to have been killed by the fall of an aërolite? Humboldt, in his *Kosmos*, mentions two such instances.

We also read in Cicero that the earthenware statue of the god (Summanus), which stood on the top of the Capitol of Rome, was shivered by lightning, and its head sent into the Tiber. Is not the distance very great? I have myself seen fragments of an elm-tree struck by lightning, in Eton Playing-fields, about ten years ago, driven to a distance of twenty-five yards. The fragments were several feet long, and some of them must have weighed ten or twelve pounds. I shall be thankful for any information on these matters. C. W. D.

NOTES

We give elsewhere an account of the Anniversary Meeting of the Royal Society last Tuesday; one of the announcements made, however, we prefer to detail here. Dr. John Davy, brother of Sir Humphry Davy, has bequeathed to the Royal Society, in fulfilment of an expressed wish of his illustrious brother, a service of plate, presented to Sir Humphry Davy for the invention of the Safety Lamp, to be employed in founding a medal to be given annually for the most important discovery in chemistry made in Europe or Anglo-America. The directions given in the will, respecting the manner in which the plate should be disposed of, have been fulfilled, and the proceeds invested in India securities, yielding a little more than 30*l*. a year. The Council will determine the form of the medal, and specify the conditions under which it will be awarded.

The Royal Institution Friday Evening Meetings are arranged to commence on the 21st of January. The evening discourses before Easter will probably be given by Prof. Tyndall, Prof. Odling, Prof. Ruskin, Dr. Carpenter, Mr. Clifford, Prof. Sylvester, Dr. Rolleston, Prof. Roscoe, Prof. Huxley, Prof. Williamson, and Dr. Blackie. The Christmas lectures (adapted to a juvenile auditory) will be by Prof. Tyndall, who has chosen Light for his subject: the first will be delivered on the 28th inst. at 3 o'clock. Arrangements have been made for the following courses before Easter:—On the Architecture of the Human Body, by Prof. Humphry, F.R.S.; on the Vegetable Products of Chemistry, by Prof. Odling, F.R.S.; on Meteorology, by Mr. Robert Scott; on Plant Life as contrasted with that of Animals, by Dr. Masters, F.L.S.; Deductions from the Comparative Anatomy of the Nervous System, by Prof. Rolleston, F.R.S.; an Introduction to the Science of Religion, by Prof. Max Müller; on the Sun, by J. Norman Lockyer, F.R.S. After Easter, the following courses will be delivered:—On the Principles of Moral and Political Philosophy, by Prof. Blackie; on Physics, by Prof. Tyndall, F.R.S.; on Astronomy, by Prof. Robert Grant, F.R.S.; on History, by Prof. Seeley.

It is now generally understood that the Earl of Dunraven will not be a candidate for the presidentship of the Royal Irish Academy, and that the Rev. Professor Jellett, B.D., will be elected. Should this be so, we may look for a great revival in the scientific forces of the Academy.

An important meeting has been held this week at Cambridge, for the purpose of considering the question of the abolition of university tests. The Master of Trinity quoted a remark made thirty-five years ago by the present Bishop of St. David's, to the effect that science, as well as literature, morality, and religion, would gain by such a measure; and from what we gather, the reading of this extract gave a tone to the meeting. Here are the resolutions passed:—Proposed by the Master of Trinity, seconded by the Venerable Professor Sedgwick: "That in the opinion of this meeting the time has come for settling the question of university tests; that the mode in which the question is dealt with in the permissive Bill introduced by Sir J. Coleridge is open to grave objections, and that any measure designed to effect such a settlement should include an enactment that no declaration of religious belief or profession should be required of any person upon obtaining a fellowship, or as a condition of its tenure." Proposed by the Master of Trinity, seconded by Prof. Maurice: "That a representation be drawn up and presented by a deputation to the Prime Minister embodying the resolution just passed; that a committee be appointed to draw up such a representation, consisting of the Master of St. John's, the Master of Trinity, the Master of Christ's, Professor Sedgwick, Professor Maurice, the University Librarian, Mr. Ferrers, Mr. Porter, and Mr. Phear; and that the representation, when drawn up, be circulated for signature among all masters, resident fellows, or resident ex-fellows, of colleges, or officers of the University or of any college."

Christ's College, Cambridge, makes a most liberal offer to students of natural science, viz. scholarships and exhibitions, in number from one to four, and in value from 30*l*. to 70*l*., according to the number and merits of the candidates; that is to say, four well-informed students may each obtain a scholarship worth 70*l*. a year, and tenable for some years. The examinations will be on April 5th, 1870, and will be open to any one, whether a member of Christ's College or not, provided his name is not on the boards of any other college in Cambridge, and provided he is not of sufficient standing for B.A. It will be open, therefore, to all undergraduates of Oxford, and to non-collegiate students of Cambridge, as well as to all students who are not members of either University. The candidate may select for himself the subjects of examination, and must send his name, &c., to the Master of the College before March 29th. Further necessary information may be obtained from the Rev. W. Gunson, Tutor of the College.

Professor Pringstein has been elected a correspondent of the Academy of Sciences of Paris, to fill the vacancy caused by the death of Professor von Martius.

We have received the following from our Dublin correspondent:—The Council of the Royal Dublin Society have appointed Mr. H. W. Dunlop, B.A. Dub., C.E., as temporary assistant librarian. The Science and Art Department, on condition that the Library of the Royal Dublin Society should be open to readers from 10 o'clock A.M. to 10 o'clock P.M. each day, Sundays and Holy Days excepted, assented to provide for the extra services of the staff of porters and for a temporary assistant librarian. Perhaps there is no other public library in Great Britain and Ireland that is so completely at the service of the public as this library; and there is none that for its size possesses a larger selection of modern foreign works on literature and science. Its great defect is a useful working catalogue, and it is to be hoped that the Science and Art Department, seeing how successfully the Committee has managed the affairs of this library, will not grudge them the small sum required to compile a catalogue. It may not be uninteresting to mention that the expense incurred in the binding of the works issued by the Patent Office amounts to an average of 50*l*. a year. The works are presented by the Patent Office to several public institutions in Ireland. But while some towns, such as Belfast, store them away in a lumber-room, in Dublin they are carefully arranged and substantially bound. The Library is now open from 10 o'clock A.M. to 10 o'clock P.M.

The Board of Trinity College proceeded on Saturday last to the election of a librarian, and, somewhat to the surprise of the literary circle in Dublin, they adhered to their ancient custom, and elected one of their own body to this important post. The newly-elected librarian is the Rev. Dr. Malet, Senior Fellow and Senior Lecturer of Trinity College. Dr. Malet is well known as a numismatist. He is the author of a catalogue of Roman silver coins in Trinity College, Dublin, and there is no doubt will make both an efficient and popular librarian. The Rev. Dr. Dickson retains his position as assistant-librarian.

A SUBSCRIPTION list has been opened for the purpose of having a model of a bust of the late Professor J. Beete Jukes, by Mr. Watkins, copied in marble, the marble bust to be placed in the Gallery containing the collections of the Geological Survey of Ireland, of which survey Mr. Jukes was so long the acting director. Subscriptions are limited to a guinea, and only about 30*l.* remains to be collected out of the 70*l.* required.

THE death is announced of M. Henry Testot de Ferry, of Bussières, near Macon, the author of more than one treatise on archæo-geology. The work by which he is best known is an illustrated quarto pamphlet, "L'Anciennete de l'homme dans le Maconnais," published in 1867, which gives an account of some of his discoveries of flint implements both in caverns and in superficial deposits in the neighbourhood of Macon. He died at the early age of 43.

A SCIENTIFIC and literary society has just been formed at Winchester. The first meeting was held in the Hall of the Mechanics' Institute on Thursday evening last, at which an inaugural address was delivered by the Rev. C. A. Johns, of Winton House. Mr. Johns, in his address, which is published in one of the local newspapers, reviewed briefly some of the latest scientific discoveries, and suggested several subjects of inquiry within the range of the members of the new society. It appears that the microscope is one of the principal instruments of research with the Winchester naturalists, and hints were thrown out how this instrument might be usefully employed in this locality for the general promotion of science. In particular, a careful examination of the chalk of the neighbourhood was recommended for the purpose of determining to what extent it differed from, or was identical with, the *Porcupine* dredgings. After the address the meeting set to work to frame laws for the government of the society. Some discussion arose with regard to the name of the society, and the admission of ladies to the meetings. It was ultimately decided not to allow ladies to attend the ordinary monthly meetings, and the name agreed upon was "The Winchester and Hampshire Scientific and Literary Society." Mr. Johns was elected president, Dr. Neal treasurer, and Mr. Angall secretary; and ten other gentlemen consented to act with them as managing committee. The use of a large room was kindly offered to the society by Mr. Savage, and as the number of members is already 50, there seems every probability that the society will flourish.

WE learn from the Viennese correspondent of the *Standard* Newspaper that Karl Vogt is giving a course of six lectures at a Roman Catholic College in Vienna, on the Primitive Condition of Man. The first lecture was attended, we are told, by a crowded and highly respectable audience.

TWO Russian travellers, MM. Ewast and Logist, have applied to their Government for a concession to work some gold fields which they say they have discovered in Lapland. They passed a month in the district in question last summer. It is almost uninhabitable, being without vegetation of any kind, and the travellers were obliged to leave it, after obtaining nearly 60 ounces of fine gold, because they had exhausted all their provisions, and none were to be had on the spot.

Land and Water announces that Mr. Frank Buckland, Inspector of English Salmon Fisheries, and Mr. Archibald Young, Commissioner of Scotch Salmon Fisheries, have been appointed by the Government to inquire into the condition of the salmon fisheries of Scotland.

ACCORDING to the *British Medical Journal* the annual salaries of the professors in the Universities of Austria are in future to be uniform—1,800 florins, with an increase of 200 florins every fifth year. Hitherto, the rate of salary has been very various; being at Innsbruck and Lemberg 945 florins, in Vienna 1,680, in Prague 1,635; with a decennial increase of 300 florins.

THE Royal Horticultural Society of Ireland have decided on holding an extra spring show in March for hyacinths and other spring flowers.

THE whales which have been lately stranded on our own shores, one at Longniddry in the Firth of Forth, another at Langstone Harbour, near Portsmouth, and others elsewhere, have given rise to a discussion which promises to become interesting. Mr. Flower holds to the Longniddry whale being either *Balænoptera musculus*, or *B. Sibbaldii;* while Professor Turner of Edinburgh, together with other eminent Scotch naturalists, incline to regard it as an undescribed species. There is, we are glad to learn, every reason to hope that the skeleton will be preserved, in which case the species will be finally set at rest. The measurements of the whale are given by *Land and Water* as follows:—Extreme length 82ft., girth 34ft., length round jaws 39ft., from front of lower jaw to back of mouth 17ft. 9in., breadth across jaws 7ft. 9in., greatest expanse of tail 15ft. 9in., length of flipper 11ft., average length of baleen 30in. to 33in.; length of calf 20ft.

IT appears from the reports of the Viennese meteorologists on the storm which broke over the Austrian capital and other parts of the empire, that it was accompanied by a very remarkable variation in the atmospheric pressure at different points close to each other. Thus, at Lesina, the pressure was 13·5 millimetres, and at Lemberg 10·7 millimetres, under the normal pressure. The greatest variation was in the district round Vienna, where the storm was most violent. Between Bludenz and Ischl there was a difference of 1 millimetre in $6\frac{1}{2}$ German miles, between Ischl and Vienna of one in $3\frac{1}{4}$, and between Vienna and Lemberg of one in 11 only. In Northern Europe the barometer was low, and the thermometer high; in Southern Europe it was the reverse.

THE *Lyttelton Times* of June last gives a report of a meeting of the Philosophical Institute of Canterbury, N.Z., at which the President, Dr. Haast, F.R.S., read a paper on the Saurian Remains lately discovered by Mr. T. Cockburn Hood, F.G.S. in that province, and taken by him to Europe. The paper was accompanied by specimens and drawings: the latter were by Mr. Triphook, and represented the most valuable of the specimens. They differed from other saurian remains, and consisted of large slabs of stone enclosing the upper and lower jaws and part of the skull of a large saurian reptile of the Amphicælian sub-order of crocodilia, to which genera Teleosaurus belonged. It was calculated to have been from 18 to 20 feet in length. The author also stated that in Mr. Hood's collection there were a great many vertebræ, in one specimen fourteen dorsal vertebræ still connected together, which, from their bi-concave character, might have belonged to the same reptile, the impression of whose skull he had exhibited. There were also many bones belonging to Plesiosaurus, of which the principal ones formed part of the paddles or fins of those marine reptiles. The paper concluded by stating that many other bones of crocodilian reptiles were included in this collection, showing that New Zealand was at one time, like parts of the northern hemisphere, the abode of numerous large reptiles.

WE learn from the *Times* of Saturday last, that Canon Greenwell has recently been prosecuting his researches in the prehistoric tumuli with great success. The barrows examined are two very large round ones near Bridlington: they contained an unusual number of secondary interments, accompanied by a fine series of implements, pottery, &c. These tumuli possess a special point of interest in reference to the apparent displacement of the primary interment. We await with interest Canon Greenwell's report on this point. It is to be hoped that the numerous human remains discovered will be described by Dr. Thurnham, or some other competent anatomist skilled in craniology.

BALLOONERS will rejoice at hearing that Messrs. Hachette and Co. have issued a magnificent work on the Aërial Voyages of Glaisher, Camille Flammarion, W. de Fonvielle, and Gaston Tissandier. The illustrations are excellent.

TWO handsome volumes devoted to the "Life and Letters of Faraday" have been issued by Messrs. Longmans, and received by us just as we were going to press. The author is the Secretary of the Royal Institution, Dr. Bence Jones, whose delightful memoir of Faraday communicated to the Royal Society last year has been perused with pleasure by all scientific men.

THE committee of the Council on Education have placed at the disposal of the University of Oxford two of the thirty exhibitions, value 25*l.* each, given by Sir Joseph Whitworth, to assist deserving students in competing for his scholarships in mechanical science.

BOTANY

Spontaneous Movements in Plants

M. LECOCQ, of Clermont Ferrand, records in the *Belgique Horticole* some singular spasmodic movements in the leaves of *Colocasia esculenta.* These motions bear no resemblance to those produced in the Sensitive plant by the warmth of the hand, but occur spontaneously independently of the action of the wind or of any external cause, at irregular intervals, and at different periods of the day and night. M. Lecocq describes the movement as a kind of trembling or quivering affecting the whole plant, sufficiently powerful to tinkle little bells attached to the branches, and on one occasion even to shake the pot in which the plant was contained, and to resist a pressure of the hand, the number of the pulsations varying from 100 to 120 per minute. He states that the *Colocasia* is destitute of the stomata with which the leaves of plants are generally provided, especially on their undersurface, and attributes the phenomenon to the incessant pulsations of the imprisoned sap.

Decomposition of Carbonic Acid by Leaves

M. P. P. DEHERAIN has been continuing his researches on the evaporation of water from the leaves of plants, and the decomposition by them of carbonic acid. His previous investigation had established the fact that these two functions of the leaves proceed *pari passu*, the same conditions favouring the one as the other; and that both are determined by the degree and nature of the light to which the leaves are exposed, and not by the temperature. He now attempts to show that it is not the intensity only of the light which determines the rapidity of the evaporation of the water, and of the decomposition of carbonic acid; but that certain rays of light are far more efficacious than others. A careful series of experiments on the submerged leaves of *Potamogeton crispus*, accurately weighing the quantity of gases emitted, showed that under the influence of yellow light 26·2 c.c. of gas were exhaled, while under the influence of blue rays of the same intensity the plant disengaged only 5·8 c.c. of gas in the same time. A repetition of the experiment established the following laws,—1st. That all the rays of light are not equally efficacious in determining the decomposition of carbonic acid. 2d. That even with the same intensity yellow and red rays act more powerfully than blue or violet. 3d. That the relation which has been established between decomposition and evaporation is maintained also with respect to the relative influence of different rays of light. [Comptes Rendus.]

New Coffee Fungus

THE Rev. M. J. Berkeley forwards to the *Gardener's Chronicle* a letter from the well-known botanist, Mr. Thwaites, of Ceylon, in which he speaks of the consternation caused among the coffee-planters of that island in consequence of the rapid increase of a parasitic Fungus in the coffee-plantations, causing the leaves to fall off before their proper time, and endangering the safety of the crop. It is a singular fact that among more than one thousand species of Fungus which have been received in this country from Ceylon this particular one does not occur; not only is it an entirely new species, but it is with difficulty referable to any recognised section, being intermediate between the true moulds and the *Uredos.* Mr. Berkeley establishes from it a new genus *Hermileia.* A. W. B.

CHEMISTRY

Thallium Salts.—II.

MM. LAMY AND DES CLOISEAUX have again examined the thallous salts named below. The *ferro-cyanide*—

$$Tl_4FeCy_6 + 2Aq.$$

has a beautiful yellow colour, a density of 4·641, and is readily dehydrated by heat. Exposed to dry air, the crystals gradually lose their transparency. Water dissolves more of this than of potassic ferro-cyanide; the actual solubility is shown by the following numbers—

100 grm. water dissolve at 18° . . . 0·37 grm. ferro-cyanide
" " " at 101° . . . 3·93 " "

The crystalline type to which this salt belongs is a doubly oblique prism. It exhibits a high degree of double refraction; fine plates of it, cut parallel to the plane of cleavage, show a well-defined system of rings under the polariser. The crystals are very fragile.

Thallous tartrates and paratartrates are remarkable for the readiness with which they yield large and brilliant crystals. *Hydro-thallous tartrate*, $C_4H_5TlO_6$, generally crystallises in beautiful white prisms, which have a silky lustre, due to the presence of a number of longitudinal striæ; it is soluble in 122 parts of water at 15°, and in 6 parts of water at 101°. The density of the crystals is 3·496, and they are, as already found by Lang, optically and geometrically isomorphous with hydro-potassic tartrate. The *neutral tartrate* is prepared by adding thallous carbonate to boiling aqueous hydric tartrate, until alkalinity ensues. On cooling, large, transparent, lustrous crystals make their appearance; their specific gravity is 4·658; they are unalterable in air at the ordinary temperature; at 100°, however, they become opaque and anhydrous. They dissolve in five times their weight of water at 15°, and in a tenth of their weight of boiling water. The formula of this salt is—

$$2[C_4H_4Tl_2O_6].\ Aq.$$

It crystallises in forms belonging to the clino-rhombic system—

Plane angle of the base . . . . 106°59′26″
Plane angle of the lateral faces . . . 101°57′41″
Obliquity of the primitive prism . . . 110°23′00″

The double refraction is very energetic. The plane of the optic axes is normal to that of symmetry. The acute bisectrix is negative and perpendicular to the horizontal diagonal of the base. The horizontal dispersion is pretty decided, as is also the proper dispersion of the optic axes, ρ being $< \nu$. *Sodio-thallous tartrate*— $C_4H_4NaTlO_6 + 4Aq.$
is prepared in the same manner as common Seignette salt, with which it agrees not only in composition, but also in figure; but it differs from that body in the orientation of its optic axes. The crystals are soluble in half their weight of water at 20°, and effloresce when handled. The acute bisectrix of the optic axes is negative and normal to the base; the dispersion, though considerable (with $\rho > \nu$), is much smaller than in the common Seignette salt. When redissolved in water, and allowed to evaporate spontaneously, the above compound yields a more complex tartrate, having the formula—

$$C_4H_4TlNaO_6 + C_4H_4Tl_2O_6,$$

and crystallising in the rhombic system. As regards form, it may be referred to a right rhomboidal prism of 98°40′, differing chiefly in height from the tartrate just described. The acute bisectrix is positive. *Thallio-stibiosylic tartrate*—

$$C_4H_4Tl(SbO)O_6 + Aq.$$

is less soluble in water than the corresponding potassic salt. The crystals are quite permanent, and have the specific gravity 3·99. Although geometrically isomorphous with the potassic salt, the two tartrates differ completely in optical properties. At 15° to 20° the optic axes are perfectly united for all the colours of the spectrum; but at 70° they separate to the extent of 20°—25°, in the plane passing through the principal diagonals of the bases of the primitive prism. Their acute bisectrix is negative; dispersion inappreciable. *Dithallous paratartrate* is anhydrous, has a density of 4·659, and is capable of crystallising in two distinct forms. The two forms, which both belong to the clino-rhombic system, are distinguished by the following numbers—

	Normal.	Irregular.
Plane angle of the base	68°55′56″	80°16′22″
Plane angle of the lateral faces . . .	90°16′24″	95° 9′36″
Obliquity of the primitive prism . . .	90°20′00″	96°45′00″

In both, however, the dispersion is weak, with $\rho > \nu$; the acute bisectrix is positive and the separation of the optic axes is considerable. Thallium has three *oxalates*, much resembling those of the potassium series; their solubility, however, increases (instead of decreasing) as the oxalic factor accumulates. The *normal oxalate* dissolves in 68 parts of water at 15°, and in 11 of boiling water. The density is 6·31. On heating, it behaves like plumbic oxalate. The crystals of this salt belong to the clino-rhombic system, but are quite unrelated to any of the corresponding potassic or ammonic oxalates hitherto described. The plane of the optic axes is parallel to the plane of symmetry; the double refraction is very energetic. *Hydro-thallous oxalate*—

$$TlHC_2O_4 + Aq.$$

crystallises in the clino-rhombic system; but its primitive form is irreconcilable with that of hydro-potassic oxalate. The specific gravity is 3·971. It is soluble in 19 times its weight of water at 15°, and in less than its weight of boiling water. There is also an anhydrous salt, whose primitive form is an oblique rhomboidal prism, likewise incompatible with the potassic salt. In both, the double refraction is energetic, and the acute bisectrix positive: but, in the former, the plane of the optic axes is parallel to the plane of symmetry; in the latter, it is normal to that plane. In the former, the proper dispersion is strong, with $\rho < \nu$; in the latter, it is weak, with $\rho > \nu$. The oxalate— $Tl_2C_2O_4 + 3H_2C_2O_4 + Aq.$ ("quadroxalate"), is closely akin to the corresponding potassic salt, both in composition and geometrical form. It shows a powerful double refraction. The plane of the optic axes is almost normal to the base. The proper dispersion of the axes is decided, with $\rho < \nu$; the acute bisectrix is negative, and very oblique to the base. The crystals are very fragile.

Thallous *picrate* is anhydrous. Its colour is yellow, when prepared with but once cooling; but, by Deville's method, this is gradually modified to a vermilion-red. At 150° the dry red salt is soon transformed into the yellow modification. Thallous picrate is less soluble than potassic picrate, one part of it requiring 280 parts of water at 15°, while potassic picrate requires 245. Its density is 3·039. Even a temperature of 270° fails to decompose it, but at 300° it detonates with violence. The red crystals are clino-rhombic; they have a vitreous lustre, and the plane of their optic axes is parallel to that of symmetry. The mean value of the index of refraction is $\beta = 1{\cdot}827$ (for the yellow line of sodium).

Reduction of Cupric Salts by Tannin

E. PALLUCCI has pointed out that tannin in all its forms reduces cupric oxide in alkaline solution, and forms a red precipitate of cuprous oxide, just in the same way as glucose does; and that the neglect of this circumstance has led to many errors in the estimation of sugar and vegetable juices, and especially in the valuation of the must of the grape: for this liquid contains the tannin derived from the skins of the grapes; and consequently, if the quantity of sugar contained in it is determined by that of the cuprous oxide thrown down, without regard to the reducing power of the tannin, the sugar in the must, and therefore also the alcohol which it is capable of yielding by fermentation, will be over-estimated. This source of error may, however, be easily eliminated by first treating the liquid under examination with basic lead acetate, which completely precipitates the tannin; the glucose may then be estimated in the filtrate.

The importance of attending to this matter in saccharimetric researches will be evident, when it is remembered that tannin is a substance very widely diffused in the vegetable kingdom; and that many vegetable substances, in which sugar is frequently sought for, contain at certain stages of their growth a quantity of tannin two, three, four, or even five times as great as that of their sugar; the greater number of fruits, not excepting the grape, belong indeed to this category. Other substances besides tannin, as for example gallic acid, pyrogallic acid, and many colouring matters, including that of wine, are also capable of reducing the alkaline cupric solution; but all these, as well as tannin, are completely precipitated by basic acetate of lead.—[Ann. di Chem. app. alla Med., Sept. 1869, p. 132.]

IN the preparation of quinine and cinchonine, a black, tarry substance is found in considerable quantity. This product, the "quinoidine" of commerce, contains a number of cinchona alkaloids, but is not used to any great extent in medicine. MM. Henry, Duguet, and Perret have much increased its value by converting the alkaloids into picrates, thus forming a mixture which can be used with advantage as a very cheap and efficient febrifuge.

GEOLOGY

The Tithonian Stage

PROFESSOR PICTET has communicated to the Swiss Society of Natural Sciences a most interesting report, containing a detailed discussion of a question which has lately acquired much importance, namely, the limitation of the cretaceous and jurassic periods. The Tithonian beds (Titonische Etage) of Oppel, as is well known, occupy a sort of intermediate position between the great jurassic and cretaceous series of deposits, and they have been referred by different authors sometimes to one and sometimes to the other of these great formations. Thus, Professor Oppel himself considered that his Tithonian stage brought the jurassic period a step forward in time, whilst M. Hébert regarded the deposits studied by him as carrying the lower part of the cretaceous formation further back. Of late years these doubtful deposits have been detected in many places, scattered from the Carpathians to the Mediterranean, through Italy, Switzerland, France, and Spain.

Professor Pictet considers that wherever these beds occur, the arrangement of the strata is in accordance with the following sectional view:—

1. Neocomian stage proper.
2. Valangian stage and marls with *Belemnites latus*.
3. Berrias limestone.
4. Tithonian stage.
5. Bed with large specimens of *Aptychus* (Kimmeridgian).
6. Jurassic fauna with *Ammonites tenuilobatus*.

The question to be settled is where, if anywhere, in this section the line of division between the jurassic and cretaceous formations is to be drawn, between 3 and 4, between 4 and 5, between 5 and 6, or finally through the middle of 4, dividing it into a jurassic and a cretaceous Tithonian.

The Stramberg limestone, which the author regards as nearly identical with the limestone of the Porte de France and Aizy, contains 55 species of Cephalopoda, of which 50 have been described as new by Zittel, whilst the other 5 have their analogues in the cretaceous period. This would seem to be in favour of the cretaceous nature of this bed; but the Brachiopoda, which have been thoroughly worked out, tell a different tale: of 38 species 26 are new, 11 belong to the jurassic period, and 1 (*Terebratula janitor*, Pict.) is common to this deposit and that of the Porte de France. It appears, however, that the strict contemporaneity of these fossils is somewhat doubtful, inasmuch as Zittel has found that the molluscan fauna of Stramberg (omitting Cephalopoda and Brachiopoda) is nearly identical with those of Wimmis and Mount Salève, which have been hitherto regarded as Corallian. But neither at Wimmis nor at Mount Salève does *Terebratula janitor* occur, nor are any of the Cephalopoda of Stramberg found there, so that it is possible the Stramberg deposit consists of two beds, of which the newer contains the above-mentioned Cephalopods and *Terebratula janitor*, and the older corresponds with the Swiss deposits at Wimmis and Mount Salève—the latter might then be the highest term of the jurassic series, and the upper Stramberg bed the lowest of the cretaceous, thus carrying the divisional line through No. 4 of the above section. M. Coquand has found the fauna of *Terebratula moravica*, which is also that of Wimmis and Mount Salève, occupying deposits in Provence which are covered by beds containing Kimmeridgian and Portlandian Ammonites, and therefore evidently jurassic. From the consideration of these facts the author infers that there have been in different regions two different orders of succession. In one (Provence, Salève, Wimmis,) the stages are nearly in conformity with those which occur in the rest of France, and the limits of the jurassic and cretaceous periods appear to be clear. In the other, included between the Carpathians and Italy (with a portion of the French Alps, &c.), the Tithonian stage prevails upon the confines of the two great periods.

By an investigation of the palæontology of the beds thus characterised as forming the Tithonian stage, Professor Pictet arrives at the following divisions in ascending order:—

1. The fauna of *Ammonites tenuilobatus*.
2. The fauna of the inferior Tithonian, known principally from Rogoznik, the blue marble of the Apennines, and probably the Tyrolese limestone with *Terebratula diphya*.
3. The fauna of the upper Tithonian or Stramberg limestone (*Terebratula janitor*).
4. The lower Neocomian stage, especially the Berrias limestone (*Terebratula diphyoides*).

Jurassic characters predominate in Nos. 1 and 2; No. 3 is rather cretaceous; hence the divisional line, *if drawn at all*, will fall between Nos. 2 and 3. But the author is of opinion that there is no necessity for drawing this line, and he remarks that the whole of the four stages are combined by strong palæontological analogies. Species pass from 1 to 2, from 2 to 3, and from 3 to 4; Nos. 2 and 3 especially, which would be separated by the line of demarcation of the two periods have about one-third of their species in common. This line would therefore be a very feeble one, and we should have to admit that in this Tithonian basin at any rate the separation of the cretaceous from the jurassic periods is singularly compromised.

[We have given so long an analysis of the argumentative part of Professor Pictet's paper, that we cannot refer to his concluding remarks, except to say that they contain some important observations on the method to be followed in geological investigations.]

PHYSIOLOGY

Reaction of Nerve-Substance.

FUNKE some years ago affirmed that nerve, like muscle, became acid after work, and at death. In this he was supported by Heidenhain, and opposed by Ranke and others. He now reasserts his former statement, using the delicate reagent *cyanin* instead of litmus, and finds strong proofs of the correctness of his views. The matter is not unimportant, as it is one of the few bases on which rests the broad general assertion that nervous [and mental] action is accompanied by material changes. [Centralbt. med. Wissensch. 1869, No. 46.]

Action of Muscarin.

SCHMIEDEBERG and KOPPE have published an account of the pharmacy and physiological action of *muscarin*, the active constituent of *agaricus muscarius* (*amanita muscaria*). This mushroom poison seems to be not unlike the Calabar bean in its action, and belladonna is in many respects antagonistic to it.

MAX SCHULTZE'S *Archiv für Microscopische Anatomie* v. 4, contains, among other papers:

"Ueber die Nervenendigung in der Netzhaut des Auges bei Menschen und bei Thieren." Von Max Schultze. Description of certain fibrillæ ensheathing the rods and cones of the vertebrate retina, and believed by Max Schultze to be the real nerve endings. An important memoir, tending to harmonise the results obtained from the study of invertebrate and vertebrate eyes. "Untersuchungen über den feineren Bau des Pancreas." Von Dr. Giovanni Saviotti aus Turin. Description by a pupil of Köllicker's, of fine intercellular passages in the pancreas, similar to those discovered by Hering in the liver. "Die haaretragenden Sinneszellen in der Oberhaut der Mollusken." Von Dr. W. Flemming in Rostock. A detailed description of certain fimbriated cells in the epidermis of acephalous mollusks, and gasteropods, not wholly unlike, and occuring in the midst of, ciliate cells, but believed by Flemming to be organs of sense. "Ueber Radiolarien und Radiolarien-artige Rhizopoden des süssen Wassers." Von Dr. Richard Greeff, Privatdocenten in Boon. Description of species of *Clathrulina*, *Acanthocystis*, and several species of new genera *Astrodisculus*, *Hyalolampe*, with discussion of their habits, anatomy, &c.

PFLUGER'S *Archiv*, ii. 9 and 10, contains:—"Quecksilberluftpumpe." Von H. Busch. A modification of the mercurial pump employed by Pflüger. The chief novelty is the occlusion of the orifices of the various parts by means of mercurial shoulder cups. "Das Unterscheidungsvermögen des Geschmacksinnes für Concentrationsdifferenzen der schmeckbaren Körper." Von Fr. Keppler in Tübingen. Keppler found it easiest to distinguish by taste variations of strength in "saline" solutions, less easy in "acid" or "sweet" liquids, and least easy in "bitter" liquids, though bitter substances (such as quinine) are those which require the smallest quantity to make a definite impression. "Ueber die Abhängigkeit der Leber von dem Nervensystem." Von E. Pflüger. Nebst Tafel II. und III. An important memoir in which Pflüger extends to the liver, the observations already made by him on the salivary glands and pancreas, affirming the direct continuation of the nerve fibres with the secreting cells. "The hepatic cell is a nucleated swelling of the axis cylinder of a nerve." Contains also many other points of interest, touching the structure of the liver, and strongly supports the views of Dr. Beale. "Ueber den Einfluss des Cyangases auf Haemoglobin nach spectroscopischen Beobachtungen." Von E. Ray Lankester. A short note affirming, in opposition to some German observers, that cyanogen forms a definite compound with Haemoglobin analogous to those of carbonic oxide, &c. "Zur Kenntniss der Wirkungen des Weingeistes." Von Dr. F. Obernier, Privatdocent und Assistenzarzt der medic. Klinik zu Bonn. A somewhat polemic paper contesting the views of Bouvier, &c., noticed in NATURE, No. 2.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, November 30.—Anniversary Meeting.—The President delivered his annual address, in which he touched upon several points of interest. One of the first subjects to which he drew attention was the Royal Society's Catalogue of Scientific Papers, the printing of which proceeds satisfactorily. He remarked: "While the aid to be derived to scientific research from the index according to authors' names is fully recognised, there can be no doubt that the value of the Catalogue will be greatly enhanced by the fulfilment of the second part of the plan announced in the preface, namely, by the publication of an *Alphabetical Index of Subjects*. The preparation of such an "*Index Rerum*" as is contemplated, has been for some time a subject of anxious, as well as careful, consideration by the Library Committee, and they have at length arrived at what, they have reason to hope, will be a most satisfactory solution of the question through a communication with Professor Julius Victor Carus, of Leipsic, who they found would be willing himself to undertake the task. I am happy to announce that the Council, acting on the recommendation of the Library Committee, have entered into a very satisfactory arrangement with Professor Carus, who will be able to commence his labours in the ensuing spring. From the well-known scientific accomplishments of Professor Carus, and his extensive experience in the peculiar work to be performed, as well as the confidence which will be reposed in him by all acquainted with the nature of the undertaking and interested in its success, we may consider the Society most fortunate in securing his services." The Meteorological Department of the Board of Trade, superintended by a Committee of the Royal Society, was next referred to; it is stated to be making good progress. Concerning the great Melbourne telescope the President remarked: "Its performance since erection does not appear to have given the same satisfaction at Melbourne that it did at Dublin; but the defects complained of may arise partly from an imperfect knowledge of the principles of the instrument and inexperience in the use of so large a telescope, partly from experimental alterations made at Melbourne, and partly from atmospherical circumstances. Those who are acquainted with the difficulties which Sir J. F. W. Herschel experienced at the Cape, will not be surprised that they should be felt at Melbourne to a much greater extent, on account of the far greater size of the speculum. But I have no doubt that if the instrument be kept in its original condition and as carefully adjusted as it was at Dublin, it will perform as well in ordinary observing weather. The high impression of its power produced by the trials which were made of it when at Dublin, is maintained by a sketch of a portion of the Great Nebula near η Argus, made by M. Le Sueur during two nights in June last. Some change in this nebula from the time when it was described by Sir J. F. W. Herschel had been indicated by Mr. Powell and other observers, though with instruments so much inferior in power to his 20-foot reflector, that little reliance could be placed on them; however, here the evidences of change are indisputable. The peculiar opening in the nebula which Sir John Herschel has compared to a Lemniscate, is still very sharply marked, but its shape and magnitude have altered. Its northern extremity is opened out into a sort of estuary; one of the remarkable constrictions seen in 1834 has disappeared, and the other has shifted its place. Two stars which were then exactly on the edges of the opening are now at some distance within the bright nebulosity; the nebula has become comparatively faint near η Argus. Another remarkable change is the formation of a V-shaped bay south and preceding the Lemniscate, whose edges are so bright that if it had then existed it could not have been overlooked in the 20-foot reflector. Another feature, which, however, was perhaps not within reach of that telescope, is an oval which M. Le Sueur describes as 'full of complicated dark markings and pretty bright nebular filaments.' The angular magnitude of the changes which have been observed, is so great as to suggest a strong probability that this nebula is *much nearer* to us than the stars which are seen along with it. It may be also noticed that M. Le Sueur saw nothing to make him believe in any development of stars in addition to those seen by Sir J. F. W. Herschel." The Council of the Society believes that an attempt to encourage and aid spectroscopic researches is an object in full unison with the highest purpose of the Royal Society's existence; and they have, therefore, after most careful deliberation, resolved to act on this conviction. A telescope of the highest power that is conveniently available for spectroscopy and its kindred inquiries is being constructed, and will be entrusted to such persons as, in their opinion, are the most likely to use it to the best advantage for the extension of this branch of science; and, in the first instance, there can be but one opinion that the person so selected should be Mr. Huggins. The President said: "The execution of this project was much facilitated by the receipt of £1,300 from a bequest made to the Society by the late Mr. Oliveira; and in the beginning of the year proposals were received from the chief opticians of the time, of which that of Mr. Grubb was accepted last April. The conditions proposed were, that the object-glass of the telescope should be of 15-inches aperture, and not more than 15-feet focus, that the arrangements of its equatorial should be such that it could be easily worked by the observer without an assistant, and that the readings of its circles could be made without leaving the floor of the observatory. Mr. Grubb was fortunate enough to secure two discs which had been exhibited by Messrs. Chance at the French Exhibition. They are of first-rate transparency, and as the construction which has been adopted admits of the lenses being cemented, this object-glass will transmit an unusual portion of light. The respective indices of the glasses were determined by making facets on their edges at an angle of 60", and observing spectral lines through the prisms thus formed with a spectroscope of such magnitude as to admit of their being placed on its table. The distinctness with which even faint lines are seen through 12 inches of the glass is a most satisfactory proof of its purity and clearness. From these Professor Stokes computed the curves for the lenses, and his numbers were almost identical with those which Mr. Grubb had obtained. I may mention that some fears had been entertained that the equality of curvature in the adjacent surfaces might *call up a ghost*, if the lenses were used uncemented, and that this has been tried and no such effect was visible. Subsequently a rather novel addition has been made, bearing upon the radiation of heat from the stars. An object-glass intercepts so much of the heat-rays that, to economise the infinitesimal effect which is expected, a metallic mirror is more promising. The equatorial is, therefore, at the suggestion of Mr. De la Rue, provided with the means of changing the 15-inch achromatic for an 18-inch reflector; and this has been accomplished by means notable for their facility and their safety. The instrument will be ready for trial in December of the present year." The rest of the address referred to the recent dredging expedition. The President then proceeded to the award of the Medals. The Copley Medal was awarded to M. Victor Regnault for the second volume of his "Relation des Expériences pour déterminer les lois et les données physiques nécessaries au calcul des Machines à Feu," including his elaborate investigations on the Specific Heat of Gases and Vapours, and various papers on the Elastic Force of Vapours. The President remarked that the name of M. Victor Regnault had been associated for the last quarter of a century with the most refined and delicate experimental inquiries connected with the measurement of heat. The amount of labour involved in his researches upon the specific heat of simple and compound bodies, upon the dilatation of gases and vapours, upon the comparison of the air-thermometer with the mercurial thermometer, upon the elastic force of aqueous vapour, upon the determination of the density of gases, and upon hygrometry, must excite the astonishment of all who could estimate the difficulty of the problems attacked, the precision of the results attained, and the fundamental character of the data which he had determined. The Council has awarded a Royal Medal to Sir Thomas Maclear, Astronomer Royal at the Cape of Good Hope, for his measurement there of an arc of the meridian. The President reminded his audience that our sole knowledge of the figure of the southern hemisphere rested on the arc of the meridian measured by La Caille, and now remeasured and extended by Maclear. The original measurement, notwithstanding the well-known ability of the great astronomer under whose superintendence it was executed, had not commanded confidence. Maclear's arc has an amplitude nearly four times as great as that of La Caille, and is, on this account, as well as on account of the greater accuracy in detail, far more deserving of confidence. The degree which is derived from it is 1,133 feet shorter than that of La Caille; and as La Caille's is 1,051 longer than that given by the spheroid, which, according to Airy, represents the average of northern arcs, it is evidently a near approximation to the truth. This is even more distinctly shown by the close agreement of the latitudes computed from the geodetic measurements with those given by the sector—that of the north extremity being 0"·4 in defect, that of the south extremity 0"·5 in excess.—A Royal Medal has been awarded to Dr. Augustus Matthiessen, F.R.S., for his researches on the electrical and other physical properties of metals and their alloys. The President remarked that these researches embraced the determinations of the specific gravities, the expansion due to heat, the thermo-electric properties, the electric conducting-power, and the effects of temperature upon the electric conducting-power. Dr. Matthiessen's investigation of the electric conducting-power of commercial copper had resulted in very great improvement of the conducting-power of the copper wire used in submarine telegraphy. Closely connected with this branch of his researches were the investigations which Dr. Matthiessen carried out for the Electrical Standard Committee of the British Association, of which he was one of the most active members. The resistance-coils issued by that Committee, which had been very generally adopted as standard instruments, were all constructed of an alloy of platinum and tin, which, after a long series of experiments, Dr. Matthiessen recommended as specially fitted for that purpose. Under the auspices of the British Association, Dr. Matthiessen undertook, a few years ago, the investigation of the chemical constitution of cast-iron, and of the influence exerted upon the physical properties of that metal by the several other elements which generally occur in association with it. He had lately elaborated a method of producing pure iron, which promised to be fruitful in interesting and important results in the hands of himself and the other chemists with whom he has been associated in this inquiry. Dr. Matthiessen's researches published in the *Philosophical Transactions*, on the action of oxidising agents upon organic bases and on the chemical constitution of narcotics (the latter investigation having been conducted in conjunction with Professor G. C. Foster), furnished proofs of the success of his labours in organic chemistry. His researches were distinguished as well for their diversity as for their uniformly complete and trustworthy character. — The following officers are elected for the ensuing year:—President: Sir Edward Sabine, L.L.D.; Treasurer: W. Allen Miller, M.D., LL.D. Secretaries: W. Sharpey, M.D., LL.D.; and G. Gabriel Stokes, LL.D. Foreign Secretary: Professor W. Hallows Miller, LL.D. The other members of the Council are: Frederick Currie, M.A.; Warren De la Rue, Ph. D.; Sir P. de M. Grey Egerton, Bart.; Professor W. H. Flower, F.R.C.S. Eng.; William Huggins; J. Gwyn Jeffreys; John Marshall, F.R.C.S. Eng.; Augustus Matthiessen, Ph. D.; Captain Henry Richards, R.N.; the Marquis of Salisbury, M.A.; C. W. Siemens; John Simon, F.R.C.S.; Archibald Smith, M.A.; Professor H. I. Stephen Smith, M.A.; Professor John Tyndall, LL.D.; and Professor Alexander W. Williamson, Ph.D.

Royal Astronomical Society, November 12.—First Meeting of Session. Mr. Warren De la Rue, F.R.S., vice-president, in the chair. The Chairman opened the meeting by referring to the illness of Admiral Manners, the president of the society, an announcement which was heard by all present with much regret. The minutes of the last meeting having been read and confirmed, and upwards of 100 presents announced, Mr. Carrington read a paper descriptive of his observatory near Farnham, Surrey, and of a variety of ingenious contrivances for securing its efficiency, and especially the correct measurement of time. Mr. Carrington intends observing with an alt-azimuth, which he has designed to ensure the comfort and consequent accuracy of the observer. The telescope-tube rotates freely on its axis, which is always horizontal; it carries the vertical circle, and in front of the object glass a right-angled prism, the front face of which may be directed on any object by the axil rotation of the tube of the telescope.—The Astronomer-Royal was then invited by the Chairman to describe his recent invention of a method of correcting the chromatic dispersion of the atmosphere. He described the various contrivances by which that object might be secured.

The simplest method of all was the employment of a series of different angles suited to the altitude of the object; but as this has some inconveniences Mr. Simms suggested the employment of an adjustable prism, as, for example, adjustable tilting of the field-glass of the eye-piece. This method, though simple, introduced undesirable optical effects. It appeared necessary, therefore, that the correction should be effected outside the eye-piece; and the best method seemed to be the combination of a convexo-concave and a convexo-plane lens, the convexity of the latter fitting into the concavity of the former, and admitting of being rotated within it, so as to vary the corrective effect according to the state of the air or the position of the object observed. Mr. Cayley, F.R.S., afterwards noticed that the desired effect could be secured by combination of two prisms, in one of which there is a convex, and in the other a concave cylindrical surface of the same curvature; when these cylindrical surfaces are made to rotate on each other, the opposite faces of the combination can assume any relative position between parallelism and an inclination equal to the sum of the refracting angles of the component prisms. Both contrivances are described in Brewster's Optics; and it is satisfactory to consider that the troublesome effect of atmospheric chromatic dispersion can be corrected effectually by contrivances so well known.—The Astronomer-Royal then invited the attention of the meeting to a proposition which had been made by the American observers, that the passage of Venus over the solar chromosphere should be observed by spectroscopists during the transit of 1874, for the purpose of determining the solar parallax. Mr. Huggins described the methods of observation available for the purpose. Mr. Proctor expressed doubts as to the accuracy of the suggested method, remarking that the phenomenon, to be observed to the best advantage, would require other stations than those selected for observing internal contacts, and that the effect of parallax, by causing Venus to cross different parts of the chromosphere, as seen from different stations, would be a fatal objection, since we have no reason for believing that the chromosphere is uniformly deep. He remarked also that we are not merely ignorant of the exact point at which Venus will cross the sun's limb, but of the angle at which her path will be inclined to the limb. Mr. Stone intimated his belief that we should find a number of difficulties cropping up around the new method, which might render observations as unsatisfactory as those made in 1769 upon the internal contact.—After some remarks by the Chairman upon the advantages of applying photography to the coming transits, a paper by Mr. Alexander Herschel, on the November meteors, was read to the meeting. Mr. Herschel shows that there is evidence of a triplicity in the meteoric stream, since in 1868 three distinct maxima were observed in England, America, and China. In 1867 and 1866 also, three maxima were observed, but they were not separated by so wide an interval.—Mr. Proctor then read a paper on the application of photography to the transit of 1874. The paper was illustrated by a chart exhibiting the passage of the earth through the shadow-cone of Venus, and showing along what lines stations should be placed, at any time, so that the relative displacement of Venus might be along a radial line of the sun's disk. By so selecting stations (or times) he remarked, the whole question would become simply one of parallax, no appreciable error would come in through misplacement of the fiducial cross-lines, and so photography would do the best work it was capable of, for determining the sun's distance. In reply to Mr. Proctor's comments on the importance of the coming transits, Mr. Stone pointed out the close correspondence of the results he has deduced from the observations in 1769., with the various other determinations of the sun's distance, and expressed his doubts whether any important improvement can be made in 1874 and 1882.—Mr. Birt then read a paper on the spots which are visible on the floor of the lunar crater Plato, of which he exhibited an interesting drawing.—Mr. Browning read a paper on the changes of colour which the equatorial belt of Jupiter has recently exhibited; and indicated the importance of a careful series of observations directed to the determination of any periodicity which may exist in these changes.—In describing the American photographs of the eclipse of last August, Mr. De la Rue remarked that they confirm the evidence already afforded by his own observations in 1860, and those of Major Tennant in 1868, that the corona, in part at least, is a solar phenomenon.—The meeting closed with an announcement on the part of the Chairman, that a medal had been struck at the Imperial Mint of France in honour of Hind, Goldschmidt, and Luther, on the occasion of the discovery of the hundredth planetoid in 1868.

Geological Society, November 24.—Prof. T. H. Huxley, LL.D., F.R.S., President, in the chair.—Robert Arnold Barker, M.D., Civil Medical Officer, Cachar, Bengal, was elected a Fellow of the Society.—The following communications were read:—(1), On the Dinosauria of the Trias, with observations on the Classification of the Dinosauria," by Prof. Huxley, LL.D., F.R.S., President. The author commenced by referring to the bibliographical history of the Dinosauria, which were first recognised as a distinct group by Hermann von Meyer in 1830. He then indicated the general characters of the group, which he proposed to divide into three families, viz.:—

I. The MEGALOSAURIDÆ, with the genera *Teratosaurus*, *Palæosaurus*, *Megalosaurus*, *Poikilopleuron*, *Lælaps*, and probably *Euskelosaurus*;

II. The SCELIDOSAURIDÆ, with the genera *Thecodontosaurus*, *Hylæosaurus*, *Pholacanthus*, and *Acanthopholis*; and

III. The IGUANODONTIDÆ, with the genera *Cetiosaurus*, *Iguanodon*, *Hypsilophodon*, *Hadrosaurus*, and probably *Stenopelys*.

Compsognathus was said to have many points of affinity with the Dinosauria, especially in the ornithic character of its hind limbs, but at the same time to differ from them in several important particulars. Hence the author proposed to regard *Compsognathus* as the representative of a group (*Compsognatha*) equivalent to the true Dinosauria, and forming, with them, an order to which he gave the name of ORNITHOSCELIDA. The author then treated of the relations of the Ornithoscelida to other Reptiles. He indicated certain peculiarities in the structure of the vertebræ which serve to characterise four great groups of Reptiles, and showed that his Ornithoscelida belong to a group in which, as in existing Crocodiles, the thoracic vertebræ have distinct capitular and tubercular processes springing from the arch of the vertebra. This group was said to include also the Crocodilia, the Anomodontia, and the Pterosauria, to the second of which the author was inclined to approximate the Ornithoscelida. As a near ally of these reptiles, the author cited the Permian *Parasaurus*, the structure of which he discussed, and stated that it seemed to be a terrestrial reptile, leading back to some older and less specialised reptilian form. With regard to the relation of the Ornithoscelida to birds, the author stated that he knew of no character by which the structure of birds as a class differs from that of reptiles which is not foreshadowed in the Ornithoscelida, and he briefly discussed the question of the relationship of Pterodactyles to birds. He did not consider that the majority of the Dinosauria stood so habitually upon their hind feet as to account for the resemblance of their hind limbs to those of birds, by simple similarity of function. The author then proceeded to notice the Dinosauria of the Trias, commencing with an historical account of our knowledge of the occurrence of such reptilian forms in beds of that age. He identified the following Triassic reptilian-forms as belonging to the Dinosauria:—*Teratosaurus*, *Platæosaurus*, and *Zanclodon* from the German trias; *Thecodontosaurus* and *Palæosaurus* from the Bristol conglomerate (the second of these genera he restricted to *P. cylindrodon* of Riley and Stutchbury, their *P. platyodon* being referred to *Thecodontosaurus*); *Cladyodon* from Warwickshire; *Deuterosaurus* from the Ural; *Ankistrodon* from Central India; *Clepsysaurus* and *Bathygnathus* from North America; and probably the South African *Pristerosaurus*.—Sir Roderick Murchison, who had taken the chair, inquired as to the lowest formation in which the bird-like character of Dinosaurians was apparent, and was informed that it was to be recognised as low as the Trias, if not lower.—Mr. Seeley insisted on the necessity for defining the common plan both of the Reptilia and of the ordinal groups before they could be treated of in classification. He had come to somewhat different conclusions as to the grouping and classification of Saurians from those adopted by the President. This would be evident, in so far as concerned Pterodactyles, from a work on Ornithosauria which he had just completed, and which would be published in a few days.—Mr. Etheridge stated that the dolomitic conglomerate, in which the Thecodont remains occurred near Bristol, was distinctly at the base of the Keuper of the Bristol area, being beneath the sandstones and marls which underlie the Rhætic series. There were no Permian beds in the area. He regarded the conglomerates as probably equivalent to the Muschelkalk. It was only at one point near Clifton that the Thecodont remains had been found.—Prof. Huxley was pleased to find that there was such a diversity of opinion between Mr. Seeley and himself, as it was by discussion of opposite views that the truth was to be attained. He accepted Mr. Etheridge's statement as to the age of the Bristol beds.—2. The Physical Geography of Western Europe during the Mesozoic and Cainozoic periods, elucidated by their coral faunas, by P. Martin Duncan, M.B.Lond., F.R.S., Secretary. The author commenced with a notice of the typical species of the coral fauna of the deep seas which bound continents remote from coral-reefs, and then made some remarks upon the littoral corals. The peculiarities of reef, lagoon, and shallow-water species were then explained, with the relations of the two faunas to one another. The author then referred to certain exceptional species, indicated the genera, the species of which constitute the existing reefs, and contributed to form those of the past, and noticed the representatives of some modern genera in old reefs. He pointed out that a correspondency of physical conditions during the deposition of certain strata was indicated by their containing analogous forms—the presence of compound cœnenchymal species indicating neighbouring reefs, and their absence in places where simple or non-cœnenchymal Madreporaria are found being characteristic of deep-sea areas remote from the coral-seas. By applying the principles thus elaborated to the evidence as to the condition of the seas of the European area from the Triassic period to the present time, the author then showed what must probably have been the physical condition of this part of the world at different periods. —Prof. Alex. Agassiz accounted for the circumscribed area of many corals in the Atlantic from the young of many coral species attaching themselves within a few hours of their becoming pelagic. He traced to the great equatorial current which must have traversed the Isthmus of Panama and the Sahara in a precretaceous period, the distribution of certain forms, which the rising of the Isthmus of Panama eventually checked. He thought that the limits of the depth at which true reef-building corals existed would be considerably extended in consequence of recent discoveries by means of dredging. He mentioned the formation of a reef at the present time off the coast of Florida, which threw light on the manner in which mudflats were formed, and the sea eventually filled.—Mr. J. Gwyn Jeffreys objected to the term deep sea being applied to a depth of ten fathoms only, when the tide in some places rose to that extent, and the laminarian zone extended to fifteen. He suggested fifty fathoms as a more appropriate measure. He remarked on the great vertical range of some simple species of corals, such as *Caryophyllia*, amounting to at least 150 fathoms from low-water mark. In deep-sea water it frequently was attached to various shells, such as *Ditrypa* and *Aporrhais*. The only other simple coral of our seas was never found at a depth of less than seventy-five fathoms. The compound corals occurred only at great depths. Dr. Duncan drew a distinction between coral-reef areas and those in which different conditions prevailed. His argument had not so much been based on the depth of the sea as on the presence or otherwise of coral-reefs. The term deep sea had been given by Professor Forbes to depths of ten fathoms and upwards. For such depths as those explored at the present day no term short of "abyssal" was appropriate. Specimens illustrative of his paper were exhibited by Professor Huxley.—The President called the attention of the Fellows of the Society to a proposed memorial to the late Baron von Humboldt, and another to the late Prof. J. B. Jukes, in aid of which contributions were desired. He referred to circulars and letters which were laid on the table, and recommended these memorials to the favourable consideration of the Fellows.

Edinburgh

Royal Physical Society, November 24.—This was the first meeting of the session. Dr. Stevenson Macadam, the President, delivered an address on the subject of Chemical Geology, in which he stated that chemistry had much to do in the explanation of geological phenomena, and though not a believer in the chemical doctrine of volcanic action as generally understood, yet he trusted to show that the geologist must accept the hand of the chemist in climbing up to an intelligent explanation of geological changes on the surface of the globe. The day has now gone by for either Plutonists or *firemen*, or Neptunists or *watermen*, to hold undisputed sway in the interpretation alike of ancient and modern changes; and the truth lies in the golden mean, and may be best sought for in the earnest endeavours to cull knowledge from all the contending elements. The first lesson which chemistry teaches us is to proceed cautiously and modestly to work. The geologist, with hammer in hand and a good share of physical force, is almost taught by the nature of his vocation to expect the same results from the same causes, operating in much the same way, and he becomes bold in theory and difficult to dislodge in his opinion; but the chemist is taught by the very nature of his science to proceed with slow and cautious steps, not only in experimenting, but also in theorising, and he learns soon that the same results need not necessarily proceed from the same causes, and that slight alterations in the mode of working may produce different results. More than that, the same results can be achieved by several modes of working. The President then alluded to chemical reaction as affecting geological phenomena; the weathering of rock masses; the influence of water holding certain gases and salts in solution on mineral substances; the production of limestone and other rocks; and the formation of coal. The effect of heat as well as water in the production of crystalline forms was alluded to, as well as the artificial formation of precious minerals, such as the ruby and sapphire. The cause of volcanic phenomena was neither solely connected with the existence of internal molten masses capable of being squeezed or blown through the external crust of the globe, nor to the presence of large quantities of the alkaline and other metals ready to be burned and ignited on the approach of water; but the President believed that the spheroidal theory of the earth's crust, propounded by himself years ago, coupled with the doctrine of the correlation of the physical forces, was sufficient to account for all volcanic phenomena. The earth is constantly under magnetic and electrical disturbance, and knowing, as can now be proven, that the physical magnetism and electricity can become heat, there seems no necessity for fancying the existence of reservoirs of molten matter waiting for ages to be discharged through the crust, or regions of uncombined chemical elements longing for water to quench their thirst. The President showed experimentally the passage of magnetism into electricity and heat, by means of large magneto-electric apparatus, which heated and fused various metals. The address concluded with reference to spectrum analysis, as indicating the composition of the sun and other stars, and as demonstrating that there is a brotherhood of matter and force throughout the universe.

The following gentlemen were elected:—As foreign members on the recommendation of the Council—Mr. C. Hitchcock, State Geologist, Vermont, U.S.; Premier Lieut. Dr. C. F. Lutken, assistant in the Zoological Museum, Copenhagen; Dr. O. A. Loweson Morch, University Museum, Copenhagen. As resident members—Mr. R. Scott Skirving, Camptown—proposed by J. M'Bain, M.D., R.N.; Mr. H. Budge, C.A., 7, Hill Street—proposed by M. R. Brown.

Dublin

Statistical and Social Inquiry Society, Nov. 23.—Robert McDonnell, M.D., F.R.S., read a paper on Patronage and Purchase in making Hospital Appointments. Dr. McDonnell condemned the system of purchase, adducing many reasons for doing so. In discussing the question he avoided all personalities, not alluding to the practice of any one hospital, but relying solely on the importance of appointments being made, not on account of the amount of money that a candidate could produce, but on account of his general ability and merits.

Paris

Academy of Sciences, November 22.—M. Becquerel communicated an eighth memoir upon electro-capillary phenomena, in which he treated of respiration, and the nutrition of the tissues, and of the muscular currents and the current of the other tissues. The author stated his principle as follows: Two different liquids, separated by a tissue, that is to say, a porous body capable of being soaked by the liquids, give origin to electrical currents resulting from the recomposition of two electricities set free in the reaction of the liquid, the walls of the capillary spaces acting as solid conducting bodies. These currents the author denominated *electro-capillary*, and the object of his paper was to demonstrate their action in the vital phenomena above mentioned, in order to establish an electro-chemical theory of life. —The dispute about wine-heating was advanced a stage by the presentation of a note from M. Vergnette-Lamotte in answer to M. Pasteur's last communication.—Of two astronomical papers by Father Secchi, the first related to the spectrum of the planet Neptune, and to some facts in spectrum analysis, and the second described a new arrangement for the observation of the spectra of the smaller stars, and referred also to the meteors of the 14th November. The author stated that the spectrum of Neptune, like that of Uranus, presents bands of absorption which do not occur in the solar spectrum. Of the three principal bands, one occurs at the limit of the geeen and yellow, about half-way between D and b; a second in the place of the line b in the solar spectrum, and the third, which is fainter, in the blue. Beyond the yellow, in the opposite direction, the spectrum suddenly terminates. The author remarked upon the accordance of this spectrum with the colour of the planet, and upon the indistinctness of its outline under high magnifying powers. The author also indicated a means of obtaining two superposable spectra, and stated that he had observed that the spectra furnished by Geissler's tubes were essentially different according as the light was taken from the tubes, the bulbs, or the luminous sheaths of the wire. In his second paper Father Secchi stated that in order to observe the spectra of the smaller stars, he had adopted the plan of placing a large prism before the object-glass of his telescope, and obtained favourable results, some of which he communicated.—A note by M. F. Massieu, supplementary to a paper presented by him on the 18th October, was read. It related to characteristic functions in thermodynamics.—M. P. Gauthier communicated an essay on the movement of a projectile in the air; M. J. Carvallo, an investigation of the stability of beacon towers: M. E. Roger, a note on some general properties of curved surfaces; MM. Curie and Vigier communicated the results of some experiments upon animals, indicating that turpentine is not, as was supposed by M. Personne, an antidote for phosphorus. They also remarked that the hypothesis that the toxical action of phosphorus is due to its depriving the blood of oxygen was not compatible with the small doses of phosphorus which may prove fatal.—A note from M. Zantedeschi on the calorific rays of the moon was read, in which he indicated that the heating effect of the moon's rays was demonstrated in 1685 by G. Montanari, and in 1781 by P. Frisi. The author also cited his own experiments.—A note on the calculation of the going of chronometers to determine longitudes, by M. H. de Maguay, was read, giving the results of observations upon these chronometers, and upon this M. Yvon Villarceau made some remarks.—A note by M. Bontemps on the coloration of glass under the influence of the solar light, was presented. In this paper the author adduces numerous examples of the production of a greater or less change in the colour of glass by long exposure to the sun's rays.—A note on the physical properties of arable soils, by M. Hervé-Mangon, was read, in which the author called attention to certain physical properties of soils, such as their calorific power, their power of condensing and holding gases, and especially their behaviour with regard to water and aqueous vapour, which are of as much importance as their chemical properties in estimating the qualities of the soils. He described the means by which these properties of soils may be investigated. —An extract from a letter by Mr. C. T. Jackson, of Boston, was communicated, giving an account of the copper-mines of Lake Superior, and of a new deposit of tin in the State of Maine. He mentioned a mass of native copper obtained at a depth of 480 feet in the Phœnix mine last June, measuring 65 feet long, 32 feet high, and 4 feet thick at the exposed end. He estimated that this mass would furnish about 1,000 tons of copper, and stated that it was contained in a true vein, cutting at right angles several beds of trap and other rocks. The gangue consisted of calc spar, quartz, and pretruite. The deposit of tin noticed by the author was said to be in the neighbourhood of the town of Winslow, where the mineral occurs in more than 40 little veins, varying in thickness from ¼ inch to 1 foot, occupying a space between the metamorphic limestone and gneiss which constitute the country. The author obtained from the rough mineral 46 per cent. of tin.—A letter from M. A. Rojas entitled "Echoes of a seismic tempest" was communicated. It contained an account of disturbances, chiefly manifested by the rise and fall of water, which occurred in various parts of South America simultaneously with the great Peruvian earthquake of the 13th August, 1868.—A letter by MM. E. Harny and F. Lenormant, dated at Thebes, was communicated, in which they announced the discovery of traces of the Stone Age in Egypt. They found an immense quantity of worked flints of all kinds upon a small space of the plateau separating the valley of Biban-el-Molouk from the escarpments which look over the ruins of Deir-el-Bahari. They compared the place to what is known in France as a "workshop of the Neolithic period."—M. Balbiani communicated an investigation of the development and propagation of *Strongylus gigas*, in which he described the production and structure of the egg, and the development of the embryo of that parasite, the embryo of which he said, remains in the egg for five or six months in winter, and may remain there for a whole year. The author described his experiments, from which it appears that this parasite does not pass directly from the egg into the animal in which it acquires its perfect development.—M. P. Fischer described the copulation and spawning of the *Aplysiæ* and *Dolabriferæ*, as observed by him in the aquarium at Arcachon. In the *Aplysiæ*, the same individual serves alternately as a male and as a female; and the author mentioned his having several times seen five or six individuals united to form a chain, each of them, except the first and last, performing the function of both sexes at once. In the *Dolabrifera*, which is likewise hermaphrodite, the copulation of the two individuals is reciprocal. The author described the emission and mode of attachment of the ribbon of eggs produced by the *Aplysiæ*, which, according to him, is sometimes as much as 120 times the length of the body of the Mollusk.—A note on the aanatomy of the Alcyonaria, by MM. G. Pouchet and A. Myèvre, was presented, as also some other papers of which the titles only are given.

ITALY

Royal Lombardy Institute of Science and Literature. The following Prize Questions are proposed by this Institute:—

ORDINARY PRIZES OF THE INSTITUTE.

Class of Literature and of Moral and Political Science.

For 1870.—To what extent is it the right or duty of Government to interfere in the education of the people, and how ought this interference to be exercised?

1. To determine whether it is a right or a duty.
2. To inquire how the exercise of such right, or the performance of such duty, can be reconciled with the acknowledged and inalienable principle of liberty, civil, political, and religious. (To be delivered in Feb. 1870.)

Class of Mathematical and Natural Science.

For 1871.—Required an Essay on the physical and chemical nature of the various mineral combustibles of different epochs, with the view of determining whether there are any means of establishing a new classification thereof, which may serve to diminish, if not to remove, the ambiguities relating to the importance of the several deposits of mineral fuel, having regard to their quality, and to the extent of their deposits. (To be delivered in Feb. 1871. Prizes for this and the preceding question, 1,200 lire.)

TRIENNIAL MEDALS OF THE INSTITUTE.

The Royal Institute of Lombardy, according to the fifteenth article of its organic regulations, "adjudges every three years two gold medals, each worth 1,000 lire, for the promotion of agricultural and manufacturing industry; one of which is intended for those Italian citizens who have contributed to the progress of agriculture in Lombardy, by means of discoveries, or of methods not yet put in practice, the other to those who have conspicuously improved, or successfully introduced into Lombardy a given manufacturing industry."

Those who wish to compete for these medals are requested to present their claims, accompanied by the necessary documents, to the Secretary of the Institute, at the Palazzo di Brera in Milan, not later than the 1st of March, 1870.

ORDINARY PRIZES OF THE FONDAZIONE CAGNOLA.

For 1870.—Required a Memoir, treating of the attained or possible advantage to the agriculture of any of the provinces of the Kingdom of Italy, and especially of Lombardy, arising from the introduction, accomplished or possible, of the doctrines or practices recommended at the present day by the progress of Physics, Chemistry, or Meteorology. (For Feb. 1870. Prize, 3,000 lire, including a gold medal, worth 500 lire.)

For 1871.—A Monograph on the poisonous and explosive substances extracted from coal, and on the hygienic measures to be adopted in the preparation, commerce, and transport of these bodies. (To be delivered Feb. 1871. Prize, 1,500 lire, with a gold medal of the value of 500 lire.)

For 1872.—A Memoir giving, together with the necessary proofs by fact, a demonstration or a refutation of the curative or prophylactic efficacy of the alkaline and earthy sulphites or hyposulphites in intermittent fevers arising from malaria, comparatively with other means or remedies already known. (To be delivered in Feb. 1872. Prize, 1,500 lire, and a gold medal, worth 500 lire.)

The Memoirs to which prizes are awarded in the ordinary competitions of the Fondazione Cagnola remain the property of the authors; but the latter are bound to publish them within a year, consulting with the Secretary of the Institute as to the arrangements and characters, and consigning to the Institute fifty copies, after which only will the money be paid.

The Institute and the representative of the Fondazione Cagnola reserve the right of printing a larger number of copies at their own expense.

EXTRAORDINARY PRIZE OF THE FONDAZIONE CAGNOLA.

For 1870.—A prize of 1,500 lire, and a gold medal of 500 lire, to the author of any work, MS. or printed, in Italian, Latin, or French, and published since 1860, which shall satisfactorily demonstrate the efficacy of any means for the cure of Gout.

The Memoirs and printed works must be presented in Feb. 1870; of the latter, two copies must be presented, with precise indication of the passages in which the discovery in question is treated. The prize may be awarded in part, and the award will take place on the 7th of August, 1870. The printing or the custody of the manuscripts to be regulated as for the ordinary prizes of the Foundation.

PRIZES OF THE FONDAZIONE SECCO-COMNENO.

For 1870.—Chemico-microscopic investigation of the curd of milk, to determine whether its active principle resides in a biological ferment, or in any other chemical agent, so as to estimate exactly the quantity required in the making of cheese. (To be delivered Feb. 1870. Prize, 864 lire.)

For 1872.—To determine, on chemical principles, and by appropriate experiments, what are the best anti-fermentatives or antiseptic substances; also the best disinfectants and deodorizers, simple or compound, indicating their various uses and relative costs, with special reference to recent investigations. (To be delivered Feb. 1872. Prize, 864 lire.)

The prize-memoir to remain the property of the author; but he must publish it within a year from the date of award, consigning eight copies to the managers of the "Ospitale Maggiore di Milano," and one to the Institute, for comparison with the MS.; after which only will the money be paid.

PRIZES OF THE FONDAZIONE BRAMHILLA.

For 1870.—Prize of 3,000 lire and commemorative silver medal to any one who, by the 30th of Nov. 1869, shall have established in Lombardy a manufacture of phosphates, prepared for agricultural use, on a scale sufficient for the manuring of at least 200 hectares per annum. (To be delivered Jan. 1870.)

For 1871.—Prize of 4,000 lire to any one who has invented or introduced into Lombardy any new machine or industrial process, or other improvement from which the population may obtain a real and demonstrated advantage. (To be delivered Jan. 1871.)

The competitors for the prizes of this Foundation must present their claims, accompanied by the requisite documents, within the time specified, to the Secretary of the "Royal Lombardy Institute of Science and Literature," in the Palazzo di Brera at Milan.

General Regulations for all the Scientific Competitions.

These competitions are open to all persons, native or foreign, excepting the actual members of the Royal Institute; the Memoirs must be written in Italian, French, or Latin, and they must be sent, post-free, at the times specified, to the Secretary of the Institute, at the Palazzo di Brera in Milan; and, according to the academic regulations, they must be anonymous, and distinguished by a motto repeated in a sealed packet, containing the christian name, surname, and residence of the author.* Particular attention is recommended to this regulation, as in default of compliance therewith, the Memoirs will not be taken into consideration.

To avoid mistakes, the competitors are also requested to state clearly *for which* of the prizes proposed by the Institute they intend to compete.

All the manuscripts will be preserved in the archives of the Institute, authors being at liberty to have copies of them taken at their own expense.

Authors of Memoirs to which prizes are not awarded are at liberty to withdraw the corresponding packets within a year after the adjudication of the prizes, which will take place in solemn assembly on the 7th of August following the close of the competitions.

* This regulation does not apply to the competitions for the extraordinary prizes of the Fondazione Cagnola, or for the prizes of the Fondazione Bramhilla.

DIARY

THURSDAY, DECEMBER 2.

SOCIETY OF ANTIQUARIES, at 8.30.—A Chalice of the Fifteenth Century, and Chalices generally; Mr. Octavius Morgan, M.P., V.P.S.A.
LINNEAN SOCIETY, at 8.30.
CHEMICAL SOCIETY, at 8.30.
LONDON INSTITUTION, at 7.30.—Architecture: Prof. R. Kerr.

FRIDAY, DECEMBER 3.

GEOLOGISTS' ASSOCIATION, at 8.
PHILOLOGICAL SOCIETY, at 8.30.
ARCHÆOLOGICAL INSTITUTE, at 4.

MONDAY, DECEMBER 6.

ENTOMOLOGICAL SOCIETY, at 7.
MEDICAL SOCIETY, at 8.
VICTORIA INSTITUTE, at 8.
LONDON INSTITUTION, at 4.—Elementary Physics: Prof. Guthrie.
SOCIETY OF ARTS, at 8.—The Spectroscope and its Applications: Mr. J. Norman Lockyer.
ROYAL INSTITUTION, at 2.—General Monthly Meeting.

TUESDAY, DECEMBER 7.

CIVIL ENGINEERS, at 8.—On Public Works in the Province of Canterbury, New Zealand: Mr. Edward Dobson, Assoc. Instit. C.E.—On Ocean Steam Navigation, with a view to its further development: Mr. John Grantham, M. Inst. C.E.
PATHOLOGICAL SOCIETY, at 8.
ETHNOLOGICAL SOCIETY, at 8.—Report on the Prehistoric Remains in the Channel Islands: Lieut. S. P. Oliver, R.A.—On the Megalithic Monuments of Brittany: The Rev. W. C. Lukis.
SYRO-EGYPTIAN SOCIETY, at 7.30.—On the Obliteration of the Name and Figure of Amun, and the Restoration of both in the time of Rameses the Second: Mr. Bonomi.

WEDNESDAY, DECEMBER 8.

SOCIETY OF ARTS, at 8.—Prints and their Production: Mr. S. T. Davenport.
GEOLOGICAL SOCIETY, at 8.—Notes on the Brachiopoda hitherto obtained from the Pebble-bed at Budleigh Salterton, near Exmouth: T. Davidson, Esq., F.R.S.—On the Relation of the Boulder-clay without Chalk of the North of England to the Great Chalky Boulder-Clay of the South: Searles V. Wood, Esq., Jun.—On the Iron-ores associated with the Basalts of the North-east of Ireland: Ralph Tate, Esq., F.G.S., and J. S. Holden, M.D.
ROYAL MICROSCOPICAL SOCIETY, at 8.—On Deep-sea Dredgings from the Vicinity of China and Japan: Prof. Rymer Jones, F.R.S.
ARCHÆOLOGICAL ASSOCIATION, at 8.

THURSDAY, DECEMBER 9.

ROYAL SOCIETY, at 8.30.
SOCIETY OF ANTIQUARIES, at 8.30.
ZOOLOGICAL SOCIETY, at 8.30.
MATHEMATICAL SOCIETY, at 8.
LONDON INSTITUTION, at 7.30.

BOOKS RECEIVED

ENGLISH.—The Life and Letters of Faraday, 2 vols.: Dr. Bence Jones (Longmans).—Ornithosauria and Reptilia from the Secondary Strata: H. G. Seeley (Deighton, Bell, and Co.).—Proceedings of the Royal Physical Society of Edinburgh, 1862–6 (Williams and Norgate).—A System of Mineralogy: J. D. Dana and G. J. Bush (Trübner and Co).—More Light, a Dream in Science (Wyman and Sons).—The Best Method of Developing the National Talent for Music: H. L. Bellini (Mallett).—The Origin of Seasons considered from a Geological Point of View: Samuel Mossman (Blackwood and Sons).—The Advanced Atlas, Progressive Atlas, Primary Atlas (W. Collins, Sons, and Co.).

AMERICAN.—Annual Report of the Trustees of the Peabody Academy of Science (Trübner and Co).

THURSDAY, DECEMBER 9, 1869

SCIENCE AND THE PUBLIC HEALTH

AMONG the wide range of subjects included in the programme of NATURE, one of the most important to mankind in general is certainly "the public health." We propose in the following article to lay before our readers an account of the way in which the attention of different nations, at various times, has been directed to this matter, until at last it is beginning to be recognised as a necessary study for all.

It would seem at first sight hardly necessary to spend words on defining the aims of a science, of which the name "Health" is so expressive, but the various writers on the subject have not thought so, and the old formula, "the art of preserving the health," has been often changed.

Londe, apparently from a dietetic point of view, says, "Hygiene is the science which has for its object the direction of the organs in the exercise of their functions," a definition which strangely limits the subject, and even excludes the most important and interesting part of it.

Oesterlen, desirous of bringing into view the two great divisions of hygiene, calls it "that part of our knowledge which has to do with the preservation and furthering of the health of individuals on the one hand, and of the community at large on the other."

Michel Lévy says that it is "the clinical study of healthy man," by which definition he wishes to individualise the more general one; but even here we do not find what we want: indeed we prefer the original definition to all these alterations of it. Dr. Parkes thinks so too, for he says, "Hygiene is the art of preserving health, that is, of obtaining the most perfect action of body and mind during as long a period as is consistent with the laws of life; in other words, it aims at rendering growth more perfect, decay less rapid, life more vigorous, death more remote."

And now we come to the extension which Bouchardat has given to the ordinary definition, "Hygiene is the art of preserving the health." But how can we preserve health? Plainly by doing our best to keep away disease. And how can we do this? By checking the causes of disease. To this end we must know these causes,—and here we have the grand object of hygiene; it is the science which studies the causes of disease, and points out the means of avoiding them.

The knowledge of causes is the great aim of all science properly so called, and no study ought to be honoured with that name which has not this end in view.

"Prevention is better than cure" is an old proverb, and, what is more, a very true one, and it is *prevention* that the hygienist studies—prevention of disease of whatsoever kind by the removal of its causes. The means by which diseases are prevented are often those which answer best for their cure; and here we perceive the link which joins hygiene with medicine, and which constitutes what we may call the therapeutical side of our science.

Thus we see that hygiene takes into consideration, incidentally as it were, and in connection with medicine, the treatment of many forms of disease by methods other than the employment of pharmaceutical preparations—these methods are what Fonssagrives calls "the Hygienic Modificators," and are such as exercise, baths, change of employment, sea voyages, residence in a different climate and above all regimen.

As the methods for the preservation of health are of the first importance to all human beings, we may expect to find provisions to this end among the writings of the ancients, especially in the codes of the lawgivers: and such is the case; take for example the writings of Moses,—they are replete with most excellent hygienic regulations, which his followers were obliged to observe under pain of severe penalties.

Look at the institution of circumcision, the provisions for the separation of the lepers from the healthy people, the command not to eat swine's flesh, the prohibition of the marriage of near relations. Besides these and many other important generalities, we find the great Hebrew legislator descending to the inmost details of family life—giving a regimen admirable in its adaptation to the climate of the countries for which it was intended; directing the burial of excrementa and refuse matter of all sorts in the earth; fixing the laws of marriage, of concubinage, of servitude, and of all social relations.

It is to the strict observation of these sanitary regulations that one of the best-known writers on hygiene of the present day, M. Michel Lévy, does not hesitate to ascribe the singular immunity of the Jewish race in the midst of fearfully fatal epidemics; which immunity was so marked in the middle ages, that it brought upon them "accusations the most absurd, persecutions the most atrocious."

We turn now for a moment to China, and find a people in many respects in a very high state of civilisation, a people who had used the mariner's compass ages before it was known in Europe; but a people who, from want of communication with other nations, have made no advance at all, perhaps, for thousands of years, who have gone on increasing in numbers at such a rate that they now form one-third of the population of the whole world, so that their country is crowded to an extent hardly conceivable. Surely we can learn something from them which will be of service to us in the management of our overgrown towns! Yes; in one thing at least they are our masters—they waste nothing; what they take from the earth they give back directly to the earth; every atom of their sewage matter is employed as manure; and how otherwise would it have been possible for so immense a population, without any external resources, to live on such a comparatively limited portion of the earth's surface, and to *keep it fertile* for so many centuries?

One of the best instances of the power of cultivation in improving the condition of a country is to be found in Lower Egypt, formerly the centre of civilisation of the world, now in a most abject condition: the inundations of the Nile, while the country was peopled with intelligent races, were the great source of its fertility, but are now the cause of the insalubrious marshes that generate the Plague, and make that country one of the most unhealthy spots on the face of the globe.

To come nearer to our own country, let us see what were the hygienic conditions of ancient Greece and Rome. Had the practical application of the principles of public health anything to do with the high state of civilisation to which those countries rose—a state which has, in some respects at any rate, never since been equalled? Had it anything to do with the success which attended the Roman armies, and led to the formation of that enormous Roman empire? Let the facts speak for themselves. What strikes one more in reading the classical authors of those countries than the continual mention of gymnasia and of baths? We find that a certain portion of time was set apart daily for bodily exercise, and thus a full development of the body was produced, and the greatest resistance given to those two great enemies of mankind, disease and death. It is true that all this training was part of a grand military system, that the youths were thus encouraged to compete for the prizes in the Olympic games and in the Roman gymnasia that they might become good soldiers; but did this prevent the cultivation of mental acquirements? Again let the facts give the decision. Do you wish to see fine buildings, buildings so well constructed that they have lasted comparatively untouched by decay for centuries? Do you wish to study beautiful sculptures, statues anatomically perfect to the minutest details, and of unsurpassed artistic elegance? You go to Athens! You go to Rome! Do not fancy that we contend for bodily exercise as against mental studies: we merely maintain that a sufficient daily corporal exercise is absolutely necessary for the proper performance of the functions, both of mind and body.

But we have not yet done with Rome. We have mentioned the baths of that city; but how were they supplied with water? Ah! here we have need to hide our faces for shame. Surely we, with all the immense advantages of scientific engineering, manage to supply our cities with water as well as the people of two thousand years ago; at any rate, with all our steam engines and manufactories, we require at least as much as they did. When we turn to the pages of Frontinus, what do we find? That at the time at which he wrote, about A.D. 92, there were actually *nine* large aqueducts by which water was brought into Rome, beside some smaller channels; these aqueducts were in some cases entirely covered over throughout their whole length, and were driven underground or supported by high arches, as occasion required. Several of them, as the Anio Vetus, the Claudian, and the Anio Novus, were from 42 to 49 miles in length, while the total length of the Marcian was actually 54 miles. The water was brought by the two Anios from the river Anio, by the others from various springs and lakes around Rome; the two newest ones, the Claudian and the Anio Novus, were made because "*seven aqueducts seemed scarcely sufficient* for private purposes and public amusements."

The supply appears to have been equivalent to more than 332 millions of gallons per day, or (since the population was certainly not more than a million) at least 332 gallons per head per day—say, six times the amount that we have now in London.

But beside the aqueducts, there was a capital system of sewers at Rome, consisting of the "Cloaca Maxima" and a series of smaller channels flowing into it. The above remarks give an idea of the admirable manner in which the means for the conservation of the public health were made a subject of State legislation in ancient Rome, and of the determined way in which all obstacles were vanquished, in order that the city might be made as healthy as possible.

Not only have we the example of the ancients in these matters, but we have hygiene reduced to a system by Hippocrates, and associated, as it should always be, with medicine. In reading his Aphorisms, one is struck by the excellent dietetic regulations which he gives, for the observance of gymnasts, and for the guidance of physicians in treating acute and chronic diseases. His third section, which treats of the influence of the seasons of the year, and of the various ages of man in the production of diseases, is also very remarkable.

The very names of the works of Hippocrates show how great a hygienist he was. "About Food," "About the Use of Liquids," "About the Diet of Healthy People," and especially his treatises on "Air, Water, and Localities," and on "Epidemics," are works which well entitle their author to be considered the father of experimental hygiene.

After Hippocrates comes Celsus, during the 1st century of our era, who devotes the first chapter of his first book "De Re Medica" to the exposition of rules concerning diet, and recommends the avoidance of too great regularity by healthy persons.

But we must not pass over the works of Galen, which were so numerous as to form a complete treatise of medicine, and which exercised so enormous an influence over the medical practice of the whole world during many centuries. Galen flourished during the latter part of the 2nd century after Christ, and was for some time physician to the gymnasia at Rome. He revived the doctrines of Hippocrates, especially the celebrated one of the four humours (blood, bile, phlegm, and atrabile), and considered that the different temperaments were produced by mixtures in various proportions of these humours with the four elements—earth, air, fire, and water, and with the four physical qualities—heat, cold, moisture, and dryness.

The Sicilian School sprang up in the 11th century, and was the offspring of the ancient Greek and Arabian medical schools. Its practice is handed down to us in a quaint Latin poem, in which a great deal of truth is mixed up with a great deal of trash, and in which we find bad therapeutics based upon faulty pathology. It is from this school that the doctrines of Hippocrates and Galen, together with the fancies of later times, were spread abroad over Europe. Thus we find that the experimental methods of the fathers of medicine were confused with a host of traditions derived from the Arabian alchemists; so that the rational methods of treatment, adopted by Hippocrates and his more immediate successors, were neglected; and diseases were treated instead by a host of supposed infallible remedies, of which the action was not at all investigated. And what do we find as the result of this change of practice? That epidemics raged with the most fearful intensity all over Europe, epidemics which were only known accidentally before, and which, finding favourable conditions for their spread in the utter neglect of hygiénic observances, came from their natural seats in hot eastern countries, and committed unheard-of ravages in Europe. Look at the Plague, that fearful epidemic of the eastern part of the Mediterranean! It is true that we have accounts of terrible visitations of it in Greece, and particularly of one which depopulated Athens in the second year of the Peloponnesian war, when the disease was introduced into that city (then fearfully overcrowded) by a ship from

Egypt, that entered the Piræus: at various times also, and particularly in the year of the city 389 (before the building of the aqueducts), the Roman capital was visited with the same calamity: but this is nothing to the fearful visitations with which all Europe was afflicted during the 14th, 15th, 16th, and 17th centuries.

The last appearance of the Plague in Europe was in 1719, when it was introduced into Marseilles by a ship that had been refused admittance into the port of Cagliari in Sardinia. Even then its course might probably have been stopped, had its malignant nature been recognised soon enough; but this was not the case, and more than 90,000 persons were killed by it. Here we have a clear proof of the value of preventive measures. Sardinia was saved because the king refused the admission of the ship into the port of Cagliari; Marseilles was ravaged because a like precaution was not taken.

In England we are accustomed to manage affairs in a less official manner than they are managed abroad, and the result is that improvements, although more difficult of introduction, are often more surely brought about with us than with our neighbours. It is certainly not because we are less hygienic in our habits than other nations, that we have so few books on hygiene, or that our Medical Schools have not looked upon it as a sister science with Medicine; but because it seemed to take no special line, and because it seemed to be so much everybody's business: now, however, since the formation of the General Board of Health and the Registrar-General's office, such a mass of information with regard to the statistics and to the causes of disease has been obtained, that it seems necessary to make a special study of this science, and no longer to allow it to be taught accidentally as an appendage to Pathology or Therapeutics.

W. H. CORFIELD

SCIENCE EDUCATION IN GERMANY

I.—THE GERMAN UNIVERSITY SYSTEM

THE most striking point of difference between the condition of science teaching in Germany and in England lies in the great facilities and encouragements which, in the former country, are given to the study of science in its highest development. In primary education, we are in England probably doing as much or more in the way of encouraging the teaching of elementary science as is being done in Germany, or elsewhere. It is our richly endowed Universities which have as yet failed to play the important part in this essential feature of modern education which, from their position and means, we have a right to expect them to do, whilst other less wealthy Colleges and educational establishments, quite as capable of giving the highest scientific instruction, have to battle with almost overwhelming difficulties. Government, on the other hand, true to its supposed function of simply assisting those who cannot help themselves, only gives pecuniary aid towards the science instruction of the working classes; and, with a singular want of foresight, provides no systematic means of training the teachers,* who are left to pick up their education as best they may.

* The few Queen's prizes and other exhibitions for instruction in the Royal School of Mines cannot in any respect be considered as a *system* of science education for teachers.

The university system of Germany is now so different in character from that of England, that it is difficult to believe that these institutions, of the same age and standing, were founded on the same type, and perhaps equally so to explain how they came to be so essentially different. The cause of this difference appears, however, to me to lie less in the necessarily varying nature of national character and requirements, than in the simple fact that in Oxford and Cambridge the system of colleges founded originally as benefactions to religious societies by private donors, and still retaining a party and religious character, has swamped (or nearly so) the university; and that the college tuition interferes with, and is indeed often absolutely opposed to, that of the proper educating body which it was intended only to supplement. In Germany the college system does not exist, and the university has always remained supreme in its locality; it knows of no interference, religious or otherwise, in its own sphere; its system of education is regulated according to one principle, and one spirit of emulation pervades the whole staff of teachers.

It is singular to notice that the German universities, which are all of them Government institutions, every professor being a civil servant of the Crown, taking the oaths and receiving salary and pension, do not suffer from what we are apt to consider the deadening influence of Government service. On the contrary, this system now holds, and has always contained, the highest and best intellectual life of the nation, replete with energy both as regards teaching power and original research. This may be explained by the fact that although the universities are State institutions, yet they are practically free as regards their internal government. Each Professor teaches as he thinks best, and Ministerial interference with the regulations of the Senate is of the rarest occurrence. In another point of view, it is well to compare the Government universities of what we Englishmen are even yet too apt to consider as the despotic and illiberal German powers with our free (!) universities. In Germany all, from prince to peasant, who choose, can and do come to the university, provided they bring certificates of having passed the exit examination of their gymnasium, as a proof of due qualification to benefit from the university instruction. Thus, the small government of Baden supports two universities, to the benefits of which persons of all classes, of all religious denominations, and natives of all countries are permitted to enter, without limitation of number, without religious test of any kind, and for the payment of ridiculously low fees. Can we say that our universities are as free? or that we in England possess any other institutions which fulfil for us the duties of these High Schools for the German people?

The university system of Germany has most certainly succeeded in stimulating intellectual activity, and fostering a spirit of original inquiry amongst the teachers, and thus creating a true profession of learned men. On the other hand, it offers sufficient inducement to aspiring students to devote themselves to special pursuits, and raise their aims to something higher than mere "Brodstudien," by opening out to them a path, often arduous and rugged, by which a man of ability may rise, from privat-docent and extraordinary professor, to the highest position of university eminence. This free infusion of new blood into the teaching staff is one great secret of the vitality of the German system; another, certainly, is the well-known principle of "Lern und Lehr-Freiheit." The professor is, on the one hand, perfectly free to treat his subject as he thinks best; and the student has a free choice amongst the various teachers of the particular department of study to which he may devote himself. Can our system, with its far larger pecuniary means, with its hundreds of scholarships and non-resident fellowships, compare in these respects, as inducing men to devote themselves to study, with the German universities?

There is no doubt that the secondary school education in England is inferior, in breadth and completeness, to the strict gymnasial system of Germany. Hence our universities are obliged to act more as finishing schools, occupied with raising the general level instead of carrying out the more scientific, higher, and more original studies which form the professional side of education, the "Fach-studien" which constitute the essential elements of the German system.

In even the smallest German university the four faculties of Philosophy (or art studies), Law, Medicine, and Theology exist in active operation. In the first of these faculties, all those students enter who desire to study either Philology and the cognate subjects, Historical science, the Mathematical sciences, or any of the various branches of Physical science.

The Law students confine themselves to their own Faculty where the theory of the profession is brought before them in a scientific order before they begin to learn the practice of the law.

In Medicine, the danger of a knowledge acquired by practice alone, and the necessity of a scientific education, are too patent to have escaped attention even in England; and hence the establishment of our numerous medical schools, attached to large hospitals. In Germany, such medical schools unconnected with other faculties are unknown; medicine forms an essential feature of every university system; and even comparatively small towns, as Heidelberg and Würtzburg, have their large and well-regulated hospitals, and are able to draw to themselves such men as Helmholtz and Kölliker. On the advantage of association of medical students with those pursuing other studies it is needless to enlarge.

In Theology there are frequently two faculties, one based upon Catholic and the other upon Protestant principles; these are found to work satisfactorily, and in Germany all who enter either Church must have at any rate gone through a regular course of theological instruction.

Another grand point in which the German university excels the English is the much larger proportion of qualified teachers which we find in the former.

As an example of the enormous teaching power in Germany, let us take the Philosophical Faculty in the University of Berlin. Here four professors and five other lecturers give twenty distinct courses each semestre (half year) in the science of Chemistry alone, including several on systematic chemistry, the history of chemistry, the chemical foundations of geology, metallurgy, pharmacy, &c. Under the head of Physics the following ten distinct courses were given by seven Professors during the summer semestre of 1868, and, in addition, a physical laboratory is conducted by Prof. Magnus:—

	Hours weekly.		Hours weekly.
Experimental Physics	4	Physiological Optics	4
Technology	5	Mechanical Theory of Heat	1
Acoustics	4	Hydrography	1
Capillary Theory	2	Physical Geography	2
Theory of Light and of Optical Instruments	2	Instruction in Methods of Physical and Geographical Observations	3

In the Biological subjects, ten professors and lecturers gave twenty-one courses, theoretical and practical. In Classics and allied subjects, thirteen professors and eight lecturers gave twenty-three courses; and on other linguistic subjects, eighteen professors and lecturers gave forty courses. In Mathematics, six professors and lecturers gave thirteen courses. In what we should call Mental and Moral Philosophy, including pædagogy, eleven professors and lecturers gave nineteen courses. In Economic and Agricultural sciences, seven professors and lecturers gave twelve courses. In History and Geography, nine professors and lecturers gave thirteen courses. In *Belles-lettres* and the Fine Arts, seven professors gave ten courses. It must be remembered that all the courses enumerated above belong to the Faculty of Arts (*Philosophische Facultät*), and are exclusive of the three other faculties, in each of which the subjects are represented in a similar proportion.

It is, of course, impossible for us in England to attempt to set up a system on this scale; but we cannot be too fully aware of the miserably insufficient way in which these studies are represented in our country; and we may rest assured that the existence, in due proportions, of a plurality of teachers is an indispensable pre-requisite for both breadth and depth of study. Where only one teacher is charged with one leading branch of study, it is barely within his power to provide the systematic teaching necessary for pass-men; whereas if, as in German universities, several teachers lecture concurrently on subdivisions of a subject, the more advanced students have the opportunity of studying more thoroughly some one section of their science. The teachers are also induced, by the opportunity of lecturing on special subjects, to engage in profounder investigations; and thus that other aim of university institutions—the advancement of science and the promotion of a learned class—is furthered. This is a consideration—at least, however, so far as England is concerned—for a remote future: it is sufficient to insist on the necessity of this plurality of teachers in order to ensure really effective teaching. The same subdivision of each subject appears in all the German universities. Thus in Göttingen, by no means one of the recently founded universities, and not subject in any special degree to those influences which have so remarkably fostered the growth of the sciences of observation and experiment, we find the following courses given in 1868:—

In Göttingen, Chemistry is (against the usage in Germany) attached to the Medical Faculty; there are, however, three divisions—the general, the physiological, and the agricultural. In the first, we find Professor Wöhler, with four skilled assistants; two of these being also professors. In the physiological division is another professor, with one assistant; and in the agricultural division, is one professor and one assistant. There are, further, four laboratory servants.

Professor Wöhler delivers the principal course of lectures on systematic chemistry. His assistants lecture on special branches.

The whole staff directs the laboratory; and over and above these are the two professors of physiological and agricultural chemistry, who conduct their own laboratories.

In Physics, Professor Weber and his assistants, Professors Listing and Kohlrausch, conduct an excellent physical laboratory, and lecture on the several branches of physics—systematic physics, optics, electricity, &c., light and heat, meteorology. Professor Ulrich treats of hydrostatics and hydraulics.

In Natural History, Professor Keferstein lectures on comparative anatomy, and performs zootomical demonstrations in the Zoological Museum during eight hours weekly to the students; for four hours weekly the Museum is open to the public, when the same Professor is present to conduct demonstrations. Two professors lecture on Botany (each six hours weekly), and combine with their lectures excursions and demonstrations in the Botanical Garden; there is also a third assistant professor. Professors Sartorius Von Waltershausen and Von Seebach lecture each four or five hours weekly on Mineralogy and Geology, and conduct practical demonstrations in the Museums.

In Heidelberg, as in Berlin and Göttingen, and in some respects even in a more perfect measure, large provision is made for the study of physical science. The *Physical Laboratory*, conducted by Professor Kirchhoff, is very successful. Once weekly Professor Kirchhoff lectures, with experiments, on a given subject; in the following week each student in the laboratory goes through the experiments for himself, and in this consists the essence of the course. Students can also prosecute independent research for several days in the week.

The *Chemical School* of Heidelberg has always been a celebrated one, and since the appointment of Bunsen to the university its renown has greatly increased. In no other European laboratory, with the single exception of that of Liebig at Giessen, have so many promising scientific chemists been trained, and this has been wholly due to the untiring interest shown in each student by the illustrious Professor, who, devoted heart and soul to his science, imparts to his students a portion of that interest in, and zeal for, original investigation, which are the real marks of a scientific spirit. Many of the chemical students at Heidelberg come, as with us, to study the science for the sake of its subsequent applications to manufactures, medicine, or pharmacy (for all the German druggists and pharmaceutical chemists are wisely compelled to attend a regular university course), but many, probably a large fraction of the number, study the science for its own sake, most of these students intending to qualify themselves for the higher posts of scientific instruction in various countries. Amongst the companions of those who studied at Heidelberg with the writer were men who are now making rising reputations in most of the German universities, or in the various institutions of France, Russia, Portugal, Great Britain, and America.

The *Physiological Laboratory*, conducted by the celebrated philosopher Helmholtz, is a novel and important feature in the Science Department in Heidelberg. A handsome and spacious building has recently been erected for the use of the Professors of Physics and Physiology. This embraces lecture-rooms, laboratories, rooms for apparatus and instruments, and for conducting special scientific investigations, besides dwelling-houses for the professors and their families.

In another article I propose to inquire more closely into the cost of establishing and working the Science Department of the German universities.

HENRY E. ROSCOE

A POINT IN MUSCULAR PHYSICS

SOME Physiologists abound in statements touching the correlation of forces in living things, and are very fond of repeating the old parallel between a muscle and a steam-engine. We have no desire to deny the aptness of the illustration, but it is as well to bear in mind that, in actual point of fact, the exact correlation of heat and mechanical force has not, as far as muscle is concerned, yet been made fully out. The point of failure is this—suppose we have two muscles: let one muscle when it contracts have to pull against a weight and so produce a decided mechanical effect; let the other muscle have no such weight to pull against, and so in contracting produce no mechanical effect (the trifling weight of the muscle itself we may disregard). According to the doctrine of the correlation of forces, the heat given out in the first case ought to be less than that given out in the second, by reason of the total force produced by the combustion of the muscle going out partly as mechanical force instead of wholly as heat. We suppose of course that exactly same amount of contraction takes place in both cases, and indeed that the muscles are perfectly identical in circumstances, except so far as their load is concerned. Heidenhain some few years ago, however, found out that there was, strange to say, more heat given out in the first case. He also discovered the reason of it, which is that when a muscle is put on the stretch, as, for instance, when a muscle has in contracting to pull against a weight, *all the chemical changes in the muscle are augmented*, and that roughly in proportion to the amount of strain.

This observation by Heidenhain seems to us one of very far-reaching and often-recurring importance, though apparently it has hardly as yet gained the attention it deserves. At all events it put a stop for a while to any satisfactory settlement of the question we are considering. Quite recently, however, Fick has devised an experiment which seemed to him to avoid the difficulty that had discomfited Heidenhain. The gist of it is simply this. He has two muscles in every way treated alike except in the following point. One muscle he allows to pull a weight up by the force of its contraction, and then lets the weight, when the contraction has passed over, pull the muscle down again. The other muscle pulls up the same weight in the same way, but at the moment that the contraction is at its maximum the weight is slipped off. The muscle then by virtue of its elasticity returns to the length natural to it when unloaded; directly it has reached this point the weight is slipped on again, and the muscle is again ready for a contraction.

It is obvious that in the first case the muscle does no actual work at all; after the contraction the weight undoes what the contraction did. In the second case, on the other hand, the weight is lifted up to a certain point and left there; real work is done.

Such being the case, the temperature of the first muscle ought to rise higher than the second; and when each muscle has been made to contract a good many times this rise ought to be appreciable. Fick finds in fact that it is so. And so we seem here to have what we desired; for both muscles *during contraction* are subject to the same strain; and hence Heidenhain's objection is obviated.

That cautious inquirer is not, however, yet satisfied. He asks "if during contraction an increase of strain produces an increase in the total chemical processes (metamorphosis) of the muscle, are we to think that the effect of the strain ceases to be felt immediately the contraction is finished, and is not carried on into the period of relaxation?

And moreover, putting the matter to an experimental inquiry, he finds, as a matter of fact, that when two muscles are treated as in Fick's experiment, one strained at all times, and the other strained only during contraction, the amount of chemical change taking place in the first, as evidenced by the generation of acid, is distinctly larger than in the second. So there the question remains for the present.

THE PROJECTED CHANNEL RAILWAYS

THE first question to be asked about a railway between England and France would be properly one upon its importance, and on the value of such a railway to the social and commercial interests of the two countries.

Let us consider the present situation and the circumstances which would affect, favourably or otherwise, a Channel Railway.

A sheet of water, impassable at all times to the bulk of a people, although a highway of their sailors, is a most effectual barrier between two countries. Free intercourse is checked; the exchange of ideas and thought limited to a small class of traders and travellers, not to mention the learned, who in all countries form but a minority of the people.

Two nations so situated are generally cold towards each other, and in time materially differ in their mode of living, in their ideas, habits, and in their institutions. A free intercourse need not necessarily obliterate the peculiarities of different races; but it has always been an effective means of moderating prejudices.

To attempt a description of the numerous and subtle ways by which the mind of populations may be taken hold of—and even be guided—would be beyond our present object; but as a means of self-education and consequent civilisation, there could not be a more powerful instrument than railways, because they offer the readiest, most convenient, and the cheapest means of communication between one individual and another.

Half-a-century ago the bulk of a nation was enclosed within its own walls; only a small minority could afford to travel and to observe, *to exchange and to induce thought.* That in which all schools must necessarily fail, or at least can succeed but indifferently—viz., the education of the million—railways are accomplishing with extraordinary rapidity; their civilising influence is constantly at work: they cover England more than any other country, and accordingly England derives all the benefit which that institution may confer on a people. Railways are also in a great measure covering France, Belgium, Germany, &c.; but there is an essential difference between the effect which they may produce in England and on the Continent. In England they interchange and mix the ideas and habits principally of the Anglo-Saxon race, some twenty odd millions; on the Continent they cause to mingle several great nations of different race: certainly more than sixty millions are there under the operation of railways as an institution.

The civilising influence of railways is, in England, accordingly confined to one groove — one main Anglo-Saxon line—and the effect on the English people cannot but remain elementary: on the Continent, however, their civilising power derives its material from several distinct and essentially different sources, viz., the Teutonic and Gallic races, and some others of minor consequence, the material of which, interwoven and allied by the affinity of thought, forms a compound of a different nature and character, differing as much as compounds differ from their elements.

That these causes have been in operation in the manner indicated, we may easily trace in the relative progress made within one generation in England and on the Continent. When railways were in their infancy, England was, in her institutions and industry, much ahead of any country. Railways have improved the condition of every people, but has the improvement not been very much greater on the Continent? It may be urged, that there was more room for improvement in those countries: that may be so, but this would not affect the case, for there was and is room enough for improvement at home.

Within one generation railways have produced wonderful revolutions on the Continent. The despotic governments of several great nations have given way to truly liberal institutions; continental industry rivals already that of England. And how was all that brought about? The immediate causes of these changes may seem innumerable; and yet, there is only one great cause at the bottom of all this change, viz. *enlightenment of the people;* and we claim a large share of this result for the institution of railways.

If, then, the combination of thought originating from different sources has so much advanced and civilised the Continent, what would be the effect upon England if a railway could suddenly bring the bulk of her people in close contact with the continental nations? A more complex, a higher compound would be formed, and what the ultimate effect of this change might be the future alone could tell; all that can be said with certainty at present is this, that *enlightenment must follow in a potential form.* Excursion trains would take the million to and from either country; excursions to and from Paris would be made with the same convenience and comfort as now between Manchester, Liverpool, London, and other large towns; in short, the social effect of the change would be immense; and how would it affect the commercial interests? Enough has already been said to show that a channel railway in good working condition would accomplish wonders, and it may be easily perceived that, though all will be gainers by the change, England would gain the most.

This being so, then, the next point is to analyse the different projects which have been proposed for bringing the result about. Among these, the Bridge scheme has naturally received considerable public attention. To the non-professional mind it appears a plausible proposition, and enough support has been given to its promoters to enable them to promise wonders.

We have no *definite* plan of the proposed bridge, but we have a Channel Bridge Company; we have not even a definite outline of the main engineering features, but we have the assurance of the success of a model which, in the opinion of the projector, might be enlarged to *any extent*. The span of the bridge is evidently not agreed upon, nor is the construction of the piers determined; we are assured that we may have any span we like, and that there is no difficulty about the piers; in fact, the only thing wanted to complete this great national work in *three* years, appears to be a subscription of eight millions sterling to the credit account of the Channel Bridge Company.

The vagueness of the scheme is the safeguard of its promoters. We cannot even describe the propositions without running the risk of being contradicted on every point; it is even intimated that it is premature to discuss the scientific questions of the Channel Bridge scheme.

We have a few facts, however, on which we may safely enlarge. It is admitted, that from Dover to Blanc Nez, a distance of twenty-one miles, a number of piers are indispensable. In 1868, the distance was to be crossed by ten spans, each over 9,000 feet in the clear, and we have a diagram of that monster bridge. In 1869 rumour will have it that the number of spans is to be increased from ten to thirty, making the reduced span still over 3,000 feet in the clear. With the first proposition we should have had nine piers, with the latter, twenty-nine, washed by the waters of the Channel.

Whatever the ultimate number of piers may be, it is evident that some of them must be constructed in water exceeding 30 fathoms, or 180 feet in depth (according to the Admiralty Chart); moreover, these piers are to be 360 feet above high water, making the total height of the structure of some of them over 540 feet from the bottom of the Channel. Let us see how one of these pyramids is to be constructed midway the Channel.

The projector discards masonry, for no operations 180 feet below water level are practicable; and as the foundations themselves would have to be carried down another indefinite number of feet, the depth and consequent pressure would render life, and therefore work, impossible.

A new construction of piers had to be invented, and herein should be found the virtue of the design; let the agents of the Channel Bridge Company tell their story:—

The project depends in effect on two remarkable innovations in the construction and establishment of the piers and metallic beams. In addition to the considerable height to which the former rise above the water (120 yards), the bases of the piers are sunk to the bottom at a depth varying from 28 to 52 yards. Except the centre one, all the piers at their foundations measure 130 yards in width and 87 yards in length, diminishing upwards, and forming at the summit a square of 66 yards on each side. The centre pier will be half as large again as the others. All the pieces composing the work are of cast-iron, and furnish, without increasing the weight, a power of resistance superior to all other kinds of construction.

As such ponderous piers could not be erected by the ordinary means, M. Boutet proposes to construct on the shore their lower parts or bases to a height sufficient to rise ten yards above high water, and as soon as the iron skeleton is put together and bolted, a number of large sheet-iron buoys are distributed about the immense surface of the base. At low water the metallic framework thus prepared is made to slide upon the shore to low-water mark. The tide, in rising, raises this raft or base of iron lightened by the buoys, and floats it. A tug steamer then removes it to its place, previously indicated by one of a line of buoys attached to an iron cable, stretched across the Straits at a depth of eighteen yards. By raising one of the buoys attached to the raft it is made to descend very slowly, the top being just above the level of the sea when the base touches the bottom. Thus are avoided all the preliminary works under water, which constitute the greatest difficulty in the way of a bridge across the Channel.

Certainly, we have here Baron Munchausen over again. These cast-iron piers, with a base of 390 ft. by 260 ft., over 200 ft. high, we are informed, are to weigh about 2,500 tons. What is the thickness of their metal to be? Information is wanting on this point; but an iron structure of these dimensions, to bed itself on the bottom of the Channel, could not be designed of less than ten times the weight named.

Assuming, for the sake of argument, that the rise of the tide would float that structure away by the means above described—and our business is to analyse the project as it is, not to suggest or attempt to improve on it—may we not ask with surprise, where would the centre of gravity of this floating structure be? Its centre of gravity would be about ninety feet above the level of the water, and at least one hundred feet *above* the centre of displacement. Why do our ships not upset, what insures their stability, and why do they right themselves? Mainly, because their centre of gravity is in its lowest position, *below* their centre of displacement. Here, however, we have a floating structure in which the centre of gravity would be enormously *above* the centre of displacement, and in its highest position. A slight oscillation, a breath of wind would overturn it, and suppose it could be floated away from shore, it would topple over—right itself upside down; the "sheet-iron buoys" would be uppermost, and the structure below them, forming a gigantic wreck somewhere in the Channel.

So much, then, about the piers. It may give the ordinary reader an idea of the character of this scheme. Shall we say anything about the 9,000 and odd feet clear span? At first sight it appears to be a typographical error; surely 900 and odd feet were meant; but then we meet with the fact of the Channel being divided into *ten* spans, so there is no getting out of it.

The whole proposition is the offspring of a highly imaginative mind. Of all the schemes or suggestions to cross the Channel by rail, this is the most incoherent. *There is nothing in it*—not one point of merit. It is not bold, because it lacks the spirit of boldness, viz. Sense. Not a trace of an engineer's mind is to be found in it. Our asylums produce innumerable schemes of this kind, but they are not permitted to disturb the public mind. It is a relief to have done with it. We are glad to say there are several projects which do not lack either sense or ability on the part of the originators. Some of them appear practicable, and one or two highly promising of success, and these will form the subject of our next communication.

DANA'S MINERALOGY

A System of Mineralogy: Descriptive Mineralogy comprising the most Recent Discoveries. By James Dwight Dana, Silliman Professor of Geology and Mineralogy in Yale College, etc., aided by George Jarvis Brush, Professor of Mineralogy and Metallurgy in the Sheffield Scientific School of Yale College. Fifth edition, 8vo. pp. 827, figures 617. (London: Trübner & Co.)

I.

FORTY years ago mineralogy was a fashionable subject in England; wealthy people collected minerals, though probably but few of those who did so ever made mineralogy a serious study. But mineralogy, under the then received doctrines of Mohs, was rather a system than a science; rather a system by which the place of a mineral in a classified list, grouped after little else than external appearances, could be determined by a few simple experiments, than a science dealing with the more subtle properties and qualities of the objects it classifies, and treating external resemblances as of no importance unless associated with analogies in composition or chemical type. No doubt it is to a great progress of mineralogy in this latter direction, associated as it has been with a corresponding development of crystallography and crystallographic optics, that the falling off in the votaries of these sciences is in a great measure due.

The mere collector for collecting's sake would prefer now-a-days to expend his money on shells or his research on fossils or plants, for a tolerable familiarity with which little preliminary education is needed, to investing his means and puzzling his mind with a science which has become a department of chemistry, and needs, besides sound chemical ideas, a thorough practical acquaintance with another and that a mathematical science, namely, crystallography.

To a similar cause is due, in part at least, the comparative indifference with which crystallography is treated by chemists and mineralogy by our geologists.

No doubt these two great sciences, chemistry and geology, between them cover nearly all the ground occupied by mineralogy. But our chemists are engrossed by great problems that may be said to be involved in the nature, if not even in the structure, of the gaseous molecule; they have hardly yet turned to that side of the problem which will one day be illustrated by the physics of the crystal molecule. So again the geologist in his character of historian of the earth is occupied with the relations of the manifold forms of life that have congregated on our globe, and their distribution in time; or else with the great dynamical causes that have engineered this "dædal earth" of ours into its present superficial form. And in England the chemical causes to which so large an amount of change in the character and bulk of rocks and in minerals is due are rarely within the grasp of our leading geologists.

In Germany it is otherwise. There, a preliminary education in mathematics or in chemistry, and by natural sequence in crystallography and mineralogy, is the almost universal introduction to the study of geology. So that to the German student, crystallography, as a science of observation with the goniometer, and of calculation with formulæ, is no rare accomplishment; and the little collection he makes during his student years, whether of minerals or of chemical preparations and crystals, forms a nucleus round which is gathered a great deal of valuable and exact knowledge, which he builds on work with his goniometer and his balance, and often with the microscope at home or his hammer in the field. The School of Mines here is producing a few men with many of these qualifications, but it may be questioned whether a more mathematical basis is not needed in that as in other similar educational institutions in England.

At any rate we do not turn out here the many-sided geologists that Germany produces, as witness the school of chemical geologists with Bischof at its head, or the admirable works on petrology by German authors; for the German geologist does not write on rocks till he has acquired a scientific acquaintance with the minerals that compose them.

In France, again, the nation of Haüy, if mineralogy, perhaps from the smaller importance of French mining industry, is not so widely pursued as it is in Germany, it has nevertheless always had its careful, thorough, and scientific votaries. Indeed, in our own day, the researches of Des Cloizeaux, following up those of Grailich, and his brilliant little constellation of Viennese crystallographers, have shown how absolutely essential is the study of the optical constants of crystals to any complete science of chemistry or mineralogy. We may, indeed, console ourselves for our shortcomings in England by the reflection that to an Englishman is due a system of crystallographic notation, and an extended use in crystallography of spherical trigonometry, which have long given to that science a greater symmetry and simplicity in its formulæ; so that now the system of Professor W. H. Miller is gradually displacing every other on the Continent.

But when we turn from Europe to America, we should expect that we should have to judge by other standards; for there a sterner call summons men to the study of mineralogy than is the case in the Old World. Where any pioneer on a new bit of mountain land may light upon mineral wealth like that of the Washoo district of the territory of Idaho, there is a need for pioneers who are mineralogists; and it is but justice to the American instinct for perceiving, and genius for supplying, whatever is wanted under novel conditions of life, to say, that in mineralogical science and mining enterprise the Americans have been equal to the demands and to the splendid opportunities that the New World has presented to them.

Of this the work, the title-page of which heads this article, is an admirable evidence. Written to meet the wants of eager and intelligent young ore-seekers in the vast stretches of plain and mountain between the Atlantic and the Pacific, it has satisfied these wants perfectly, and helped to produce (we had almost written has produced) an admirable American school of mineralogists. But it has done more than this: it may almost be called the text-book of mineralogy for Europe; and it is so for the reason that its ingenious and talented author is laborious; and is not only laborious, but able to throw off a prejudice like an old garment. It is this freshness of mind and power of work that has made the successive editions of his mineralogy not only *not* reprints, but essentially original books, and even made them an interesting pyschological study of one who may be taken as a typical American man of science.

The chief features that distinguish the large and handsome volume representing Professor Dana's new, that is to say, his fifth edition, are—Firstly, modifications in his system of classification; Secondly, alterations in the nomenclature; and Thirdly, a new chemical notation. Professor Dana still retains his peculiar graphic method for the representation of the zones of crystals and his notation for their planes. Both of these, we believe, he will discard in some future edition which we earnestly hope that he may live to carry through. The notation is rather complicated than simplified by the employment as symbols of the letter *i* in its different phases of italic and capital, which, together with the figure 1, are used to represent what, in fact, are the most frequently recurrent and concurrent planes of a crystal. The far greater elegance of the stereographic projection for the representation of the zones of a crystal than the sort of contracted and symbolised Quenstedtian method employed by Professor Dana will certainly prevent this latter from ever becoming adopted in other works. Passing from the crystallographic to the chemical notation, we may say that Professor Dana accepts a sort of nuclear theory of chemical combination, and illustrates this by a corresponding notation. As, however, the use of this system is only partially introduced into the work, we may dismiss it with the remark that, inasmuch as the use of formulæ of one shape or another to express a particular compound can only be a relative and not an absolute expression of the modes in which its elementary units are combined, when one such formula or system of formulating is to be conventionally selected for adoption, that will be the best to select which expresses best the relations between the compounds from the point of view of the author employing them. Professor Dana's does not seem to us to meet this requirement as from the point of view of the mineralogist.

N. STORY MASKELYNE.

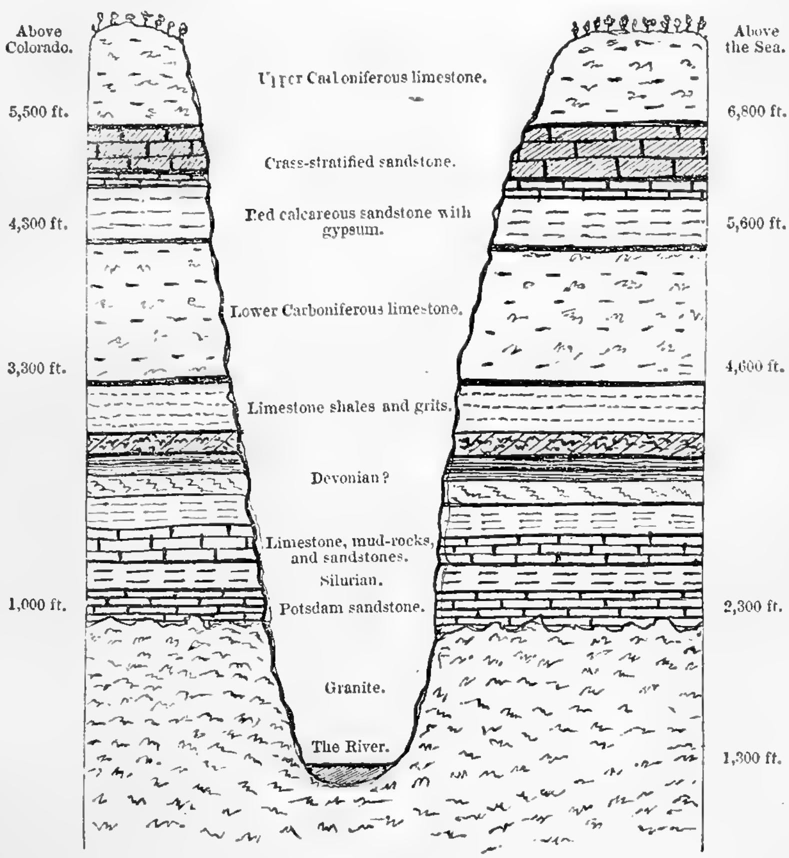
BELL'S NEW TRACKS IN NORTH AMERICA

New Tracks in North America: A Journal of Travel and Adventure in 1867–68. By W. A. Bell, M.B., F.R.G.S., &c. With a map, 20 lithographs, 22 woodcuts, and 3 botanical plates. 2 vols., 236 and 322 pp. (Chapman & Hall.)

THIS is an unusually important book of travels, giving interesting particulars of the vast wild Western country which, though still the home of the Apache and the Buffalo, is every day being more and more brought into subjection by the settlers, traders, miners, capitalists, and railways of the "Anglo-Saxons" of America, as Dr. Bell calls them.

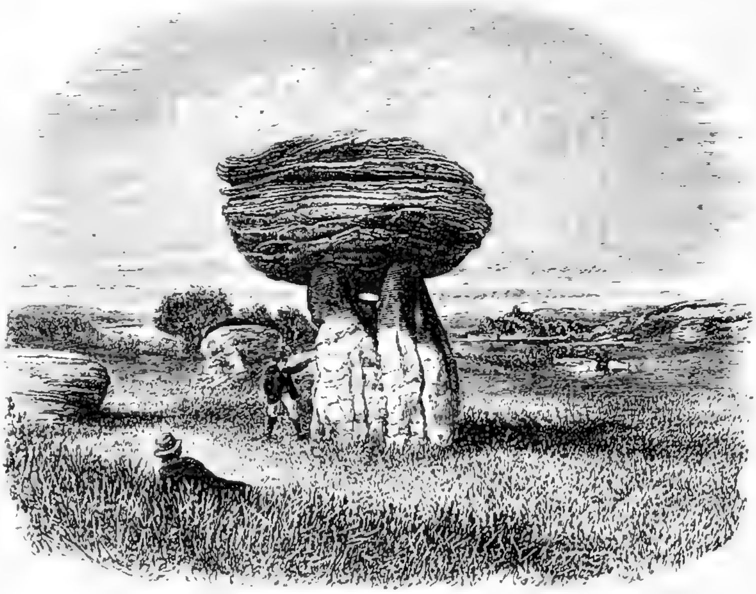
The author was well placed for obtaining reliable information, having been attached in 1867 to the surveying expeditions of the Pacific Railway as photographer and physician. In this manner he travelled "about 5,000 miles beyond the pale of civilisation and railways." His contributions to the physical geography of the astonishing country south-west of the Rocky range are carefully done. He writes a brief treatise on the natural drainage system of the district, and especially of the Great Basin, which is considerably larger than France, and so-called because none of its rivers reach the sea. The reason of this is not that it is a basin with a rim all round to act as an insurmountable barrier to drainage, but rather because it is in reality a collection of hundreds of smaller basins, each of which has its stream and lake, which lose by evaporation and percolation what is supplied by the limited rainfall. Cultivation is, however, increasing the rainfall in Utah, and the Great Salt Lake has consequently of late years been steadily rising. The rainfall from year to year is irregular. At Fort Yuma, on the borders of California and Arizona, it was in four recent years 0·33, 8·57, 4·20, and 2·94 inches. Irrigation must be resorted to for all agricultural operations.

The barren, monotonous mountain ranges of the great basin are rich in minerals. One silver lode, the Comstock, yields annually four millions sterling, or more than all the mines in Mexico, and Nevada furnished twenty million dollars of gold in 1867 to California's twenty-five. Copper and iron are also plentiful, and the unworked coal-fields are numerous. Hydraulic power is now employed in mining in California. The machine used was invented in 1852 by one Mattison, of Connecticut, and directs a stream of water from a two-inch pipe under a pressure of perhaps 200 ft. perpendicular, which gives a tremendous force, against a bank or hill-side, containing *placer* gold, tearing down the earth into the washing sluices



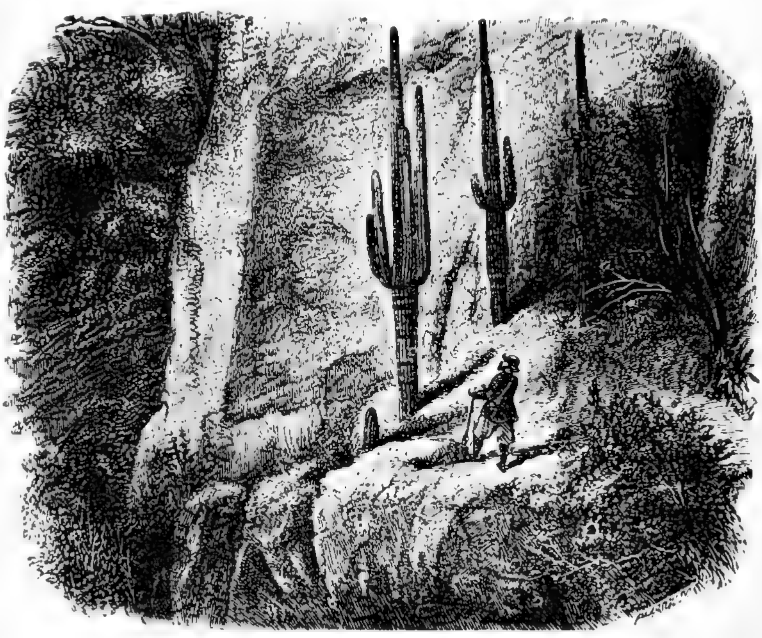
SECTION OF THE CANON OF THE COLORADO ON THE HIGH MESA, WEST OF THE LITTLE COLORADO (BY J. S. NEWBERRY, M.D.)

with great rapidity. This powerful agent is stated to be changing the face of the country: obliterating valleys, levelling hills, turning rivers from their course, and covering fertile tracts miles in extent with bare heaps of gravel.



MUSHROOM ROCK

The most distinctive features of the great basin are the cañons, those narrow, deep, abrupt, and continous chasms at the bottom of many of which run rapid rivers, unapproachable by man or animal. They are due to the action of water, being formed by the passage through a dry region of never-failing and rapid streams, coming from distant sources exterior to the dry country. The water has worn its way in some instances through 1,000 ft. of granite. Where these deep cuttings abound, the country is sterile, for they drain it to the uttermost, and the streams lie far below the reach of surface animal or vegetable life. One cañon, that of the Purgatoire, has been so named because of the "bright, fiery-red sandstone" of which its walls are composed; the effect of the mass of colour is said to be wonderful. In another, the Aravaypa, a cliff below the average, was measured, and found to be 825 ft. high.



THE CEREUS GIGANTEUS

Here, when the sun had left the upper world, and night had really come, the blackness of darkness around was something awful, and the stars which covered the narrow streak of sky above seemed to change the heavens into a zigzag belt, every inch of which was radiant with diamonds.

In the valley beyond this cañon, nearly all the water of the Aravaypa sinks into the earth. But the cañon of cañons is the great cañon of the Colorada, discovered by Lopez de Cardenas in 1540, which is but 100 feet wide at its narrowest, while its greatest depth has been barometrically ascertained to be 7,000 feet, or one mile and a third. The sun only shines into this terrible chasm for an hour a day, and it is 550 miles long. At its bottom runs the swift river from which it takes its name. The account which Dr. Bell gives of James White's flight for life down this previously unexplored cañon on a raft, makes a wonderful sensation story, which appears to have found believers. We reproduce from Dr. Bell's book a geological section of this remarkable gorge.

The alkali flats form another distinctive feature in the basin. They are covered with salts, usually nitrate of soda, and being perfectly barren, form white glistening sheets which, in the dry unsteady atmosphere of the desert, become tantalising mirages. The plateaux of the basin region were the last portions of the West which were raised from the sea; even now subterranean fires are active, and it is quite possible that gradual upheaval may be still going on. Earthquakes are frequent; mud-volcanoes are still to be found in places; huge surface cracks have occurred within the memory of living men, and Dr. Bell counted 52 jets of steam issuing from the ground in one valley. A considerable number of the known species of cactus are found about the Mexican boundary line; of one of these, the *Cereus giganteus*, which is sometimes called the Monumental cactus, we give an illustration: the mistletoe grows in the same region. We also give an engraving of the "Mushroom Rock," one of the many similar monuments, denuded and abraded by water, which are to be found in the arid plains of Kansas. Dr. Bell's book contains thoughtful matter on the Indian races of the past and present sufficient for a monograph on the subject. He writes briefly and sensibly on the Mormons, denying the common assertion that Salt Lake City, setting aside polygamy, is a moral place, and stating that there is an entire absence of religious devotion. The Joe Smith anti-polygamy party are making rapid strides, especially in the numerous outlying settlements in Utah and Nevada.

OUR BOOK SHELF

Lehrbuch der Chimie, *gegründet auf die Werthigkeit der Elemente.* Von. A. Geuther, Prof. in Jena. Erste Abtheilung. (Jena: Dœbereiner, 1869.)

THE doctrine of Quantivalence plays a most important part in the general theory of modern chemistry; but when carried out to the extreme lengths which Dr. Geuther claims for it, this doctrine, so useful in the classification of elements, fails altogether to bear an original meaning. The following is an extract from a table, on page 16 of the above-named work, showing the Quantivalence of the elements according to Geuther:—

H = 1

As	V. III. I.	Na	V. IV. III. II. I.
Ba	II. I.	Os	VIII. VI. IV. III. II.
Br	VII. V. III. I.	S	VI. IV. II. I.
Cs	V. IV. III. II. I.	N	V. III. I.
Cl	VII. V. III. I.	Ag	IV. II. I.
Cr	VI. IV. III. II.	K	V. IV. III. II. I.
Fe	VI. IV. III. II.	Mn	VII. VI. IV. III. II.
Fl	(VII.) (V.) III. I.	I	VII. V. III. I.

Here, for example, we find potassium described as acting as a monad, a dyad, a triad, a tetrad, and a pentad element, and chlorine as a monad, dyad, triad, pentad, and heptad element. What does this do more than express, in a roundabout and inconvenient way, what Dalton long ago enunciated as combination in multiple proportions—that great law round which the whole structure of the science is built up?

The doctrine of Quantivalence is, in strictness, only applicable in the case of gaseous elements and compounds; bodies whose molecular weight can be estimated by their vapours obeying Avogadro's law of volumes, viz. that the molecule of an element or compound is that weight of the body which occupies in the gaseous state the volume of hydrogen gas weighing 2: the Quantivalence of an element being determined by the number of atoms of hydrogen or of chlorine, or other distinctly monad element or radical, which it may be able to take up in this molecular volume. By an extension of this reasoning, we term potassium a monad and barium a dyad metal, because we find that they each form only one compound with chlorine, potassium combining with one atom and barium with two; and we assume that KCl and $BaCl_2$ represent the respective molecular weights of the compound. Many metals, doubtless, may be considered to exhibit a variation in Quantivalence: such as iron in the ferrous and ferric chlorides; mercury in Hg_2Cl_2 and $HgCl_2$: though this difference may be also explained in the case of mercury by the two atoms of metal being joined together. But to term chlorine a heptad because it forms the compound $HClO_4$, or potassium a pentad because we know of the body K_2S_5, appears to be an exaggeration of a useful doctrine almost as unphilosophical as the divisible atoms of M. Delavaud. Apart from these views, Prof. Geuther's book will be welcomed by all chemists as containing clear and concise descriptions of many compounds not mentioned in other manuals, which are of much importance for the theory of modern chemistry. H. E. ROSCOE

Parasitology.—*Zeitschrift für Parasitenkunde.* Herausgegeben von Dr. E. Hallier und Dr. F. A. Zürn. Band I. Zweites Heft. 8vo. pp. 126, with 2 Plates, price 3*s*. (Jena, 1869. London: Williams and Norgate.)

THERE can be no more conclusive evidence of the vigour with which scientific researches are pursued in Germany than the fact that a circulation is found for a periodical publication devoted entirely to the study of parasites, animal and vegetable. We find in the present number reports of observations on the *Aspergillus glaucus*, and two other newly-discovered parasitic Fungi, found in the passages of the ear, and connected with certain forms of deafness, and a description of a cure in the case of the former species by the external application of alcohol. The greater part of the number is devoted to a dissertation by Dr. Hallier on the parasites of infectious diseases. A portion of this paper is occupied by a discussion whether the minute *Myxogastres* found on decayed wood, grass, &c., belong to the animal or vegetable kingdom. Since the only high authority who has maintained the animal nature of these parasites, Dr. de Bary, in opposition to Fries, Berkeley, and others, has since apparently altered his views, the question may now be considered as disposed of. If the apparent spontaneous motion of the young germinating spores of *Trichia* and other Fungi be considered proof of an animal nature, the same argument must be applied to the zoospores of certain Algæ. A. W. B.

Serials

Hardwicke's Science Gossip, for December, contains, among others, articles on the employment of wild flowers for decorative purposes (in gardens), on the invasion of lady-birds, on the structure of the hairs of plants, on variations in the *Primulaceæ*, on the influence of food and light on *Lepidoptera*, and on the natural history of the Ruff and Reeve.

The *Monthly Microscopical Journal* for December (No. 12) contains some remarks on the nineteen-band test-plate of Nobert, and on immersion lenses, by Mr. J. J. Woodward, United States Army; a paper on high-power definition, with illustrative examples, illustrated with a plate of test-objects, by Dr. G. W. Royston-Pigott; and one entitled "My Experience in the Use of various Microscopes," by Dr. H. Hagen. These relate to the instrument and its use. The papers devoted to subjects for investigation are—one by Mr. Staniland Wake, on the Development of Organisms in Organic Infusions, and further remarks on the Plumules or Battledore Scales of some of the *Lepidoptera*, by Mr. John Watson, the latter illustrated with a plate. The Microscopical Society's Proceedings contain some interesting remarks on the Scales of the *Thysanura*, in connection with Dr. Pigott's paper.

The recent numbers of the *Revue des Cours Scientifiques*, a periodical which is hardly so well known in this country as it deserves to be, and which is intended to furnish a general weekly statement of the proceedings of the principal scientific societies both in France and in other countries, contain translations of Dr. Christison's historical account of the operations of the Royal Society of Edinburgh from 1783 to 1811; of Sir Roderick Murchison's anniversary address to the Geographical Society in May last; and of the first of Dr. Bence Jones's lectures on Matter and Force, delivered before the Royal College of Physicians. Of foreign scientific doings, we find a translation of Carl Vogt's paper on the Primitive History of Man, read before the meeting of German naturalists at Innsbrück, and M. Vulpian's lecture on Pathological Anatomy, delivered at the Faculty of Medicine in Paris.

THE DEEP-SEA DREDGING EXPEDITION IN H.M.S. "PORCUPINE"

NATURAL HISTORY (*continued*)

THIS being a preliminary report, I will make only a few remarks as to the Mollusca obtained in the expedition, and with respect to that part of the sea-bed which I investigated :—

1. *The Mollusca are mostly Arctic or Northern.*—This I have shown in my narrative as regards the western coasts of Ireland, which have hitherto been supposed to belong zoologically to what Professor Edward Forbes called the "Lusitanian" province ; and the present remark applies not only to deep water, but to shallow water, and even the bays. In Prof. Wyville Thomson's cruise to the south-west of Ireland occurred two species, which I was quite unprepared to see. These were *Solarium Siculum*, and an unmistakeable fragment of *Cassidaria Tyrrhena*. The former inhabits the Mediterranean, Madeira, Canaries, and the coast of Portugal ; and the latter has not been noticed north of Brittany. Such exceptions, as well as *Ostrea cochlear*, *Murex imbricatus*, and *Platydia anomioïdes*, it is difficult to account for ; but as all these species are said to inhabit deep water, the Equatorial current may have carried them northwards in an embryonic state ; or it is possible that they may be likewise Northern species, and have not yet been discovered in high latitudes. We are nearly ignorant of the Arctic Mollusca, owing to the difficulty of exploration ; and those who assume that the marine fauna of the circumpolar seas is poor or wants variety, ought to see the vast collection made by Prof. Torell at Spitzbergen. The greatest depth at which he dredged there was 280 fathoms. The soundings taken in 1868 by the last Swedish Expedition reached 2,600 fathoms, when a *Cuma* and a fragment of an *Astarte* came up in the *Bulldog* machine. Soundings, however, are very insufficient for zoological purposes. Judging by the results of our own expedition this year, which have increased to such a wonderful extent our list of the British marine fauna living beyond the ordinary line of soundings, it may fairly be taken for granted that the Arctic marine fauna is much less known than ours. I have not the slightest doubt that by another expedition to Spitzbergen, provided with improved machinery, and under the charge of the Professor at Lund or some other able zoologist, the species obtained would be double the present number. It is evident that the majority, if not the whole of our submarine (as contradistinguished from littoral or phytophagous) Mollusca originated in the North, whence they have in the course of time been transported southwards by the great Arctic current. Many of them appear to have found their way into the Mediterranean, or to have left their remains in the tertiary and quaternary formations of the south of Italy ; some have even migrated into the Gulf of Mexico, as I will presently mention.

I cannot see much (if any) difference between the Mollusca from the warm and cold areas of Dr. Carpenter. The number of species from the cold area, which also occurred in the warm area, is forty-four. Other species from the cold area, and not from the warm area, are eleven. Of these last, five are undescribed, and one is apparently sub-fossil and may be a relic of the glacial epoch ; so that there remain five only which are Arctic and North-American, but which were not found in the warm area.

2. *Additions to the British Mollusca.*—Although I am aware that the discovery of what are called "new" species does not rank high as a scientific fact, it is still interesting to all zoologists as well as collectors ; and it must not be forgotten that the important subject of zoö-geographical distribution depends in a great measure on such discoveries, and especially on the relation of any local fauna to other faunæ. The number of species new to our seas and procured in this expedition is no less than 117. Of these, fifty-six are new to science, and eight were supposed to be extinct as tertiary fossils. Sixteen genera are new to the British seas, including five which are undescribed. Some of the species and genera, however, are represented by single specimens, and a few by fragments. These whet one's appetite instead of satisfying it. The total number of species of our marine Mollusca, inclusive of littoral species but exclusive of the Nudibranchs (none of which latter were met with except in the bays), is 451, according to the latest work on the subject, 'British Conchology :' so that more than one-fourth has been added in the course of a few months. All that I could do by continual dredgings in comparatively shallow water during the last sixteen years was to add about eighty species to the number described by Forbes and Hanley. I regard the present (although a large) addition as merely an earnest of future acquisitions. Almost every square mile of the sea-bed yields different species, some being apparently local or restricted in their distribution. In fact the treasury of the deep is inexhaustible.

3. *Relation to North-American Mollusca.*—The late Dr. Gould, in his 'Report on the Invertebrata of Massachusetts' (1841), gave 176 species of marine Mollusca as inhabiting that coast. Mr. Mighels, Prof. Stimpson, and others have since described a few more species, making the total number about 200. I attifie; leas 6ohaieddnts of these as British, a dozen being from the present expedition. The size of North-American specimens is, so far as I have observed, smaller than that of our specimens of the same species, perhaps showing that their common origin was in the Arctic seas of Europe and not of America.

4. *Relation to Mediterranean Mollusca.*—In my last Report on Shetland dredgings, published a short time ago by the British Association, I discussed this subject so fully that it is needless to go further into it, except by calling the attention of the Society and all scientific men, particularly geologists, to the importance of ascertaining what has caused or is still causing the remarkable concordance which is observable between the marine Mollusca in the deeper parts of the North-Atlantic and Mediterranean. I cannot help now thinking that this concordance may be explained by the existence of an undercurrent into the Mediterranean through the Straits of Gibraltar, being probably a branch of the great Arctic current. Dredging researches ought to be carried on in the lower part of the Bay of Biscay, and off the coasts of Portugal and Spain into the Straits for the purpose of determining this vexed and highly interesting question. Dr. Carpenter's last cruise to the west of Shetland, at a depth of 290 fathoms added a remarkable species to our Mollusca in *Platydia anomioides*, a rare Mediterranean Brachiopod. The specimen is twice the size of those from the Mediterranean. *Octopus Cocco* of Verany is another remarkable discovery, and was dredged in 345 and 632 fathoms between latitudes 60° and 62° N. It was only known as Mediterranean, where it is stated by Verany to inhabit a depth of 100 mètres or nearly 55 fathoms. The dimensions of our largest specimen of this Caphalopod considerably exceed those given by Verany. I may here mention that my friend Captain Spratt, who co-operated with Prof. Edward Forbes in his Ægean exploration, has most obligingly placed at my disposal a very small quantity of material which he dredged in 1846, forty miles east of Malta, at a carefully ascertained depth of 310 fathoms. It contains among others the following remarkable species of Mollusca, all of which were found in the Porcupine expedition, and may be considered northern forms :—*Leda pellucida* (Phil.), *Leda acuminata* (Jeffr. M.S.), *Dentalium agile* (Sars), *Hela tenella* (Jeffr.), *Eulima stenostoma* (Jeffr.), *Trophon Barvicensis* (Johnst.), *Pleurotoma carinata* (Biv.), and *Philine quadrata* (S. Wood). This shows how imperfect is our knowledge of the Mediterranean fauna.

5. *Relation to Mollusca of the Gulf of Mexico.*—I hope soon, through the kindness of Professor Agassiz, to have an opportunity of examining and comparing the Mollusca dredged during the last three summers by Count Pourtales in the United States expeditions. The only species which I have yet seen from the Gulf of Florida are *Waldheimia Floridana* and *Terebratula Cubensis.* The former appears to be that variety of *Terebratula septata* (a Norwegian and now British species), which Professor Seguenza has described and figured under the name of *Waldheimia Peloritana*, from tertiary beds in Sicily; and the latter is closely allied to *Terebratula vitrea* (Mediterranean), and is perhaps a variety of that polymorphous species. Not only the external characters, but also the skeletons or internal processes of these American species correspond exactly with those of their European relatives. I must repeat that I am no believer in the doctrine or idea of species being "represented" in a geographical point of view. Species may be identical or allied, but not "representative."

6. *Gulf Stream.*—The northern character of the marine fauna observed during the Porcupine expedition is certainly at variance with the general notion that this "river in the ocean," or any branch of it, flows directly to our coasts; and I have elsewhere * endeavoured to show that the occurrence in northern latitudes of tropical shells, seeds, and timber may be accounted for by the surface-drift arising from the prevalence of westerly winds. But there is unquestionably a marine as well as an aerial circulation, Equatorial and Arctic currents as well as Trade winds.

7. *Nature of the sea-bed.*—In that part of my Report which contains a narrative of the expedition, so far as I was engaged in it, I have given some particulars which it is unnecessary to recapitulate. Some of the pebbles and gravel from my deepest dredgings (1,215 to 1,476 fathoms) have been examined by Mr. David Forbes, the eminent mineralogist; and he has kindly furnished me with the detailed report which I append to this communication. Among the pebbles and gravel were several fragments of true volcanic lava, which throw a considerable light on the course of the Arctic current along the western coasts of Ireland. He is of opinion that these volcanic minerals came from Iceland or Jan Mayen. Mr. Forbes has also, at my request, carefully and completely analysed a portion of the Atlantic mud from 1,443 fathoms, the pebbles and gravel having been previously removed from it by sifting; and the result shows that its chemical composition differs greatly from that of ordinary chalk. The sifted mud contains out of 100 parts 50·12 only of carbonate of lime, and no less than 26·77 of fine unsoluble gritty sand or (rock débris); while chalk consists almost entirely of carbonate of lime, and seldom contains more than from 2 to 4 per cent. of clay, silica, and other foreign material. But I do not say that this single analysis is conclusive. Mr. Forbes's further report on that head, as well as on a specimen of Rockall (for which I am indebted to Staff-Commander Inskip, who procured it in the Porcupine surveying expedition of 1862), also accompany this communication. I may observe that stony ground did not occur during the present expedition beyond about 550 fathoms, the sea-bed at greater depths being covered by mud or what is technically called "ooze." This superstratum appears to consist chiefly of decomposed animal matter mixed with the shells of Pteropods and *Globigerinæ*, which must have dropped from the surface of the sea. I have myself seen living *Globigerinæ* in great abundance taken with *Spiriales* in the towing net; and Major Owen's papers in the Journal of the Linnean Society for 1865 and 1866 leave no doubt not only that *Globigerinæ* and other free Foraminifera live on the surface of the mid-ocean, but that they have the power, by protruding their pseudopodia, of descending a few inches and rising again to the surface. Sessile or fixed Foraminifera, of course, cannot do this; but I have found some of these living on the surface and attached to floating sea-weed (*Fucus serratus*) at a considerable distance from land. The fresh appearance of the sarcode in Foraminifera taken from great depths does not of itself prove that they live there, when we consider the comparatively antiseptic or preservative property of sea-water as well as the extremely minute size of the aperture in each cell which contains the sarcode. Some Foraminifera, however, inhabit only the bottom of the sea.

8. *Bathymetrical conditions.*—So much has been said of late years (by myself among others) as to the depths of the sea being not merely inhabited but replete with life of a highly organised nature, and as to there being apparently no bathymetrical limit of habitability, I will content myself with noticing the Mollusca which were dredged in 2,435 fathoms. They were—(1) *Pecten fenestratus*, a Mediterranean species; (2) *Dacrydium vitreum*, Arctic; (3) *Scrobicularia nitida*, Finmark to Sicily; (4) *Neæra*, an undescribed species, Norwegian; and (5) *Dentalium*, a fine species, also undescribed. The first of these species was known to inhabit depths varying from 40 to 60 fathoms, the second 50 to 300 fathoms, the third 3 to 300 fathoms, and the fourth 50 to 60 fathoms. The *Dentalium* is an inch and a half long; and in 1,207 fathoms was taken a new species of *Fusus*, living and two inches in length. This last species, being one of a zoophagous tribe, must have had for its food prey of a suitable kind and perhaps of dimensions at least equal to its own. Abysmal life is not represented merely by microscopic organisms; and I suspect that there is no difference in size between the animals that live in shallow water and the greatest depths. Nor do I believe that such abysses are dark or devoid of light. Colour is assuredly not wanting, nor the usual organs of sight in the Mollusca and Crustacea. Living specimens of the *Dacrydium* from 2,435 fathoms are reddish-brown; and a fine live specimen of *Trophon latericeus* from 440 fathoms is bright rosecolour. *Dacrydium vitreum* makes a nest (like that of *Modiolaria discors* and *Lima hians*) consisting of a narrow tubular case twice as long as itself. This case is lined with a delicate membrane, and covered with small Foraminifera, particles of sponge, and coccospheres, which are firmly agglutinated. The *Dacrydium* inhabits the broader half, its front or ventral margin lying in the direction of the opening of the case. From 2,090 fathoms came a new species of *Pleurotoma*, alive, and having a pair of prominent eyes on short stalks; and the *Fusus* from 1,207 fathoms was similarly provided. In both these genera the eyes are perfect and not rudimentary. The eyes of the *Oncopus* from 632 fathoms are remarkably large and more highly organised than those of many fishes. The animals of this genus crawl with their arms, head downwards; and the common species (O. *vulgaris*) buries itself in sand and gravel. Instances to prove that colour and visual organs are possessed by animals at very great depths are innumerable; and they would lead us to infer that light (of what nature I cannot suggest) penetrates the sea to its profoundest base. None of the deep-sea animals appeared to be phosphorescent. Perhaps in the next expedition some photometric apparatus may be devised in order to solve this problem.

9. *Oceanic currents.*—The Arctic or Northern current probably runs with greater rapidity and force in some places than in others, where the flow seems to be very slow and feeble. Everywhere (as I pointed out in my Shetland Report for 1863) the motion must be extremely gentle or imperceptible at the bottom in deep water, as we find the most fragile and delicate corallines from stony ground quite uninjured.

10. *Geological considerations.*—Not the least interesting fact derived from this expedition was the discovery, in a living or recent state, of species hitherto supposed to be-

* "British Conchology," vol. i. Intr. pp. xcviii. and xcix., and Report of British Association, 1868, p. 236.

long exclusively to the tertiary formation and hitherto considered extinct. Such are *Leda excisa* of Philippi, and an undescribed species of the same genus (Calabrian and Sicilian fossils), *Scalaria corrugata* of Brocchi (Subapennine), *Kellia pumila*, *Neæra jugosa*, and *Cerithium granosum*, all of S. Wood (Coralline Crag), and an undescribed species of *Fusus*, which I propose to name *Sarsi*, lately found in the Red Crag. Mr. Wood is inclined to refer this last species to *F. Spitzbergensis* of Reeve; I regret that I cannot agree with him in such determination. Our Coralline and Red Crag beds notoriously contain a large proportion of northern species; and I was not far wrong in regarding the former as the "cradle" of the British Mollusca. I may here remark that, as in Shetland, valves and fragments of *Pecten Islandicus*, *Tellina calcaria*, and *Mya truncata* var. *Uddevallensis* (all Arctic species) were dredged in rather deep water, on the western coasts of Ireland; and a perfect specimen of *Leda arctica* was found in Loch Torridon. These shells are apparently in a semi-fossil condition; but it is impossible to say whether they are quaternary or recent.

As regards marine zoology, this expedition has produced results more important than those which have ever been obtained in any previous expedition of the kind by the enterprise of our own or any other nation; and I cannot help expressing a fervent wish that it may be renewed next year. The United States, France, Sweden, and Norway are prosecuting with great success this line of scientific research; and I feel confident that Great Britain, with her vast wealth, naval resources, intelligence, energy, and perseverance, will keep the lead which she has now taken.

As one of the naturalists who were privileged to assist in the late expedition I shall be happy again to place my humble services at the disposal of the Royal Society in continuation of the work, especially in conjunction with Dr. Carpenter and Prof. Wyville Thomson.

J. Gwyn Jeffreys

*** At the Meeting of the Royal Society at which the observations described in the above paper were communicated, Professor Alexander Agassiz gave an account of the principal results arrived at by the American Dredging Expedition. The ground explored was limited to a length of about 120 miles by 60 to 90 miles in width between the Florida Keys and the Northern Coast of Cuba, and although the depth reached was by no means as great as that attained by the last British expedition, not being much more than one-third of it, about 820 fathoms, yet the results were fully as striking, and agree in the main points with the conclusions arrived at by the English explorers. Commencing with the sponges, which contained a great number of siliceous forms, he gave as the results of the examination of Dr. Oscar Schmidt, of Graatz, the specific identity of the majority of the species with Mediterranean, Azoric, and Atlantic species, showing a geographical range quite unprecedented, and extending the Atlantic fauna from the Gulf of Mexico to the Bermudas, the Azores, the Mediterranean, the Western Coasts of Europe, and extending far north to the boreal regions of Norway, Iceland, and Greenland. These same results would apply, as far as the collections have been examined, to the Echinoderms, Mollusca, and Crustacea, though the number of identical species in these branches over this extensive Atlantic area is much smaller. Among the Echinoderms, the *Echini* specially showed several new and interesting forms, recalling types characteristic of the cretaceous period; one genus especially, the genus *Salenia*, is represented in our seas by a most interesting species. Another cretaceous type, a new genus of *Spatangida* (Pourtalesia) was found in deep water in Florida, and like the Crinoid genus *Rhizocrinus*, was also dredged by the Porcupine expedition. Several other species of Echinoderms were also shown to be identical on both sides of the Atlantic.

Prof. A. Agassiz gave besides an instance of one of these so-called cretaceous generic types, which was only the young stage of a well-known genus represented from the time of the chalk through the tertiaries, and which is now found living in the tropical seas, showing how careful we ought to be in our generalisations when drawn from a class where the transformations from the young stages to the adult are as great as they are in Echinoderms. He gave as an example of this the case of two species of Echini, one of which is known under one generic name (*Stolonoclypeus*), as the adult, in Florida, while the young is known under a different generic name (*Echinocyamus*) in Europe, and endeavoured to explain by the action of the currents the migration of the pelagic embryos, many of which remain in a helpless condition for several months, and thus to show how changes of currents, brought about by the elevation or subsidence of portions of continents, would fully account for the present limitation of marine faunæ. The presence of corals at great depths will also materially alter the views generally received of the depth at which reef-builders may work, and modify to a certain extent Darwin's theory of the reefs, and their mode of growth. Prof. A. Agassiz alluded to the probable continuation of the exploration of the Gulf Stream by Prof. Pierce, the superintendent of the W. S. Coast Survey, who was carrying out the plans laid out by his predecessor, Professor Bache; and trusted that the Coast Survey would carry on the investigations so successfully inaugurated, thanks to the enlightened views of Professor Pierce, and the executive ability of the assistant in charge, Count Pourtales. This exploration would consist of a series of normals to the coast of the United States, extending from Georgia to New York, completely across the Gulf Stream, thus extending sufficiently far north to meet upon a common ground the English expedition, which the British Government could not fail to send in consequence of the brilliant results of the two previous years.

SCHOLARSHIPS AND EXHIBITIONS FOR NATURAL SCIENCE IN CAMBRIDGE

THE following is a list of the scholarships and exhibitions for proficiency in natural science, which are likely to be offered in Cambridge during the ensuing year.

Trinity College.—One of the value of about £80 per annum. The examination (in chemistry, physics, physical geology, including meteorology and the elements of mineralogy) will be in Easter week, and will be open to all undergraduates of Cambridge and Oxford. Further information may be obtained from the Rev. E. Blore, tutor of Trinity College.

St. John's College.—One of the value of £50 per annum. The examination (in chemistry, physics and physiology, with geology, anatomy, and botany) will be on 29th and 30th of April, and will be open to all persons who are not entered at the University, as well as to all who have entered and have not completed one term of residence. In this College, moreover, natural science now is made one of the subjects of the regular college examination of its students at the end of the academical year (in May); and exhibitions and foundation scholarships will in consequence be awarded to students who show an amount of knowledge equivalent to that which in classics or mathematics usually gains an exhibition scholarship in the College. In short, natural science is on the same footing as classics and mathematics, both as regards teaching and rewards.

Christ's College.—One to four, and in value from 30*l.* to 70*l.*, according to the number and merits of the candidates, tenable for three and a half years, and three years longer by those who reside during that period at the College. The examination will be in April, 1870, and will be open to the undergraduates of Christ's College; to non-collegiate undergraduates of Oxford; to all undergraduates of Oxford; and any students who are not members of either University. The candidates may select their own subjects for examination. Besides these there are three other exhibitions perfectly open, which are distributed annually among the most deserving students of the College.

Clare College.—One of the value of 50*l.* per annum. The examination (in chemistry, chemical physics, comparative anatomy, physiology, and geology) will be on March 30th, and will be open to students intending to begin residence in October. The candidates must show such acquaintance with classics and mathematics as will qualify them to pass the previous examination.

St. Peter's College.—One of the value of 60*l.* per annum. The examination (in chemistry, botany, comparative anatomy and physiology) will be in June, and will be open to all students who are not members of the University, or who have not commenced residence in the University.

Downing College.—One or more, according to the merits of the candidates, of the value of 40*l.* per annum. The examination (in chemistry, comparative anatomy, and physiology) will be in March, and will be open to all students not members of the University, as well as to all undergraduates in their first term.

Sidney College.—Two of the value of 40*l.* per annum. The examination (in heat, electricity, chemistry, geology, physiology, botany) will be in October, and will be open to all students who may enter on the college boards before October 1st.

Although several subjects for examination are in each instance given, this is rather to afford the option of one or more to the candidates than to induce them to present a superficial knowledge of several. Indeed, it is expressly stated by some of the colleges that good clear knowledge of one or two subjects will be more esteemed than a general knowledge of several.

Candidates, especially those who are not members of the University, will in most instances be required to show a fair knowledge of classics and mathematics; such, for example, as would enable them to pass their previous examination.

There is no restriction on the ground of religious denomination in the case of these or any of the Scholarships or exhibitions in the university or the college.

Further necessary information may be obtained from the tutors of the respective colleges.

It may be added that Trinity College will give a fellowship for natural science once, at least, in three years, and that most of the colleges are understood to be willing to award fellowships for merit in natural science equivalent to that for which they are in the habit of giving them for classics and mathematics.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents.*]

Mental Progress of Animals

I HAVE failed to meet with a satisfactory treatment of this subject either in works of mental philosophy or natural history. Sir John Lubbock, in "Prehistoric Times," refers to the likelihood of the sagacity of man and the wariness of animals proceeding *pari passu;* but he does not develop the idea or aid it by illustration, and I find that the tradition still widely prevails that the instinct and intelligence of animals is a thing fixed and unchangeable; and that the mammals which roamed over the world during the earlier and middle tertiary epoch must be credited with the same amount of sagacity as their representatives of the present day. Such statements are assumptions opposed to the current of any facts we possess on the subject. Much of what has been termed *cunning* in animals will be found to have been very much sharpened and made evident in quadrupeds and birds, owing to the new necessities imposed upon them by man the tamer or man the destroyer.

For it is under one of these two characters that man approaches animals, affecting them in the most complex and vivid manner. No bird or quadruped so high in the mental scale as the dog, horse, rat, rook, or sparrow, has been found in the lonely oceanic isles or in any region free, or all but free, from human influence; not because in these quarters such animals could not exist, but rather it would seem because the aboriginal fauna had no opportunity for the improvement of its wits by coming in contact with an enemy or friend so complex, dreadful, and ingenious as a human being.

One of the first impulses communicated to the wits of the wild animals is that derived from the sense of new wants. Now, this is what man supplies by his cultivated fruits and cereals. A feast is spread before quadrupeds and birds more generous than that of nature. But this banquet is guarded, and often becomes a baited trap in which the simple thief is caught; but a very slight increment of sagacity is sometimes enough to turn the scale, and this quickness of wit, especially in the first ages of society, as among existing savages, would be slowly met by improvement of trap. Necessity—on either side the mother of invention—would at last permit only wary vigilant enemies, since these alone could succeed, to hang round the skirts of kraals and wigwams, approach in twilight the crops near stockaded villages, prowl about places of interment, lodge in sewers, enter cellars; and, keenly alive to every sign of danger, multiply in spite of poison, trap, and gun, and in defiance of trained animals of their own and allied species, and that division of labour which gives us special hunters.

The fear of man is a slowly acquired instinct. Mr. Darwin, in his account of his travels, gives some interesting instances of the fearlessness of birds little exposed to man in South America. The crew of Byron's vessel were astonished at the manner in which the wolf-like dog of the Falkland Islands approached them merely out of curiosity. Compare these traits with the admirably organised expeditions for plunder of baboons, elephants, &c., and the rude customs acted upon for self-preservation of the half-wild dogs of the Peninsula and the East, wherein the care of the weak and young, the usefulness of sentries, the value of signals, the difference between sham and real danger, and the advantage of confusing traces of retreat, seem all to be known, and it will be pretty evident that man the thinker has to a considerable extent reacted on animals wild and domestic. Even in my own quarter it is the steady belief of the shepherds that the common sheep-dog has progressed in intelligence and docility within the last fifty years by careful selection. "Where the dog is not valued for intelligence, as in some Eastern countries, it is a much more stupid animal than with us."

Now were we in vision to behold that wonderful Miocene age, when the great mammals roamed over Europe unpeopled as yet by man, I am convinced that both they and the birds of the period would be less interesting and more monotonous in their habits than those which people Europe at the present day, and have for ages been engaged in a struggle for existence with a being so much superior to themselves; and that in prehuman times the horn, hoof, tooth, and coat of mail, to a far greater extent than now, ensured victories which other and more subtle agencies are now necessary to secure on the part of those animals nearest to man in organisation and habits.

Nov. 21 J. S.

The Suez Canal

I NOTICE in your number of 4th inst. an article relating to the Suez Canal (by Mr. Login, C.E., late of the Ganges Canal), and shall be glad if you will allow me to make a few observations with reference to it.

In making his suggestions, Mr. Login appears to have overlooked the fact that there is already a sweet-water canal connecting the Nile with the centre of the isthmus, and passing through the Wadi Toumilat, which it has watered and fertilised; and, further, that it is proposed, when the actual work of excavation in the maritime canal is completed, to commence irrigating operations on a large scale by means of this canal.

As to diverting the Nile, or one of its mouths, and thereby forming the great maritime canal, that is quite another affair. In the first place, if I remember rightly, the water in the present sweet-water canal, where it meets the great canal, is some twelve feet above the level of the latter—in other words, above the level of the sea. Does Mr. Login think, then, that to carry the water at this level for 50 or 60 miles across and above the shallow lakes of Menzaleh and Ballah and the plain of Suez would have required *less* excavation than the actual scheme? In the second place, as Mr. Login says, there would be locks at either end of the canal, which would be not only costly, but most inconvenient for ships in their passage. In the third place I doubt very much whether the whole stream of the eastern branch of the Nile would suffice to keep the canal and the great Bitter Lakes full. Some time ago, indeed, it was disputed whether the Mediterranean and the Red Sea *together*, pouring into the Bitter Lakes, would raise them to the level of the sea, owing to the influences of absorption and evaporation. The facts, however, proved to the contrary.

Still, Mr. Login is much more ambitious. With a *single* stream (that is to say, taking the eastern branch of the Nile at Damietta), less in volume than the present maritime canal, he proposes not only filling the Bitter Lakes to the level of the sea, but raising them to a level of at least twelve feet beyond it (thereby nearly doubling their present volume). Lastly, if the canal and Bitter Lakes could be filled sufficiently by the Nile spring the dry season, it would be overflowing during the floods, and if it could be filled only in the season of the floods, in the dry season it would be nearly empty.

As to the question of breakwaters at the Mediterranean end, Mr. Login rightly says that the annual deposit along the coast is hardly perceptible. I cannot see, therefore, what improvement the breakwaters he suggests would be upon the present ones, seeing that the easterly current *now* passes the extremity of the west pier with a speed of two or three miles an hour. He therefore not only proposes sending a current of at least five miles an hour for a considerable distance up the canal (as his plan infallibly must)—rendering it in strong prevailing winds almost impossible to get out from between his breakwaters—but also sacrificing a splendid harbour of 550 acres in extent.

I quite agree with Mr. Login in thinking that the Suez Canal will not only outlive all abuse, but become one of the greatest blessings to the civilised world.

Birkenhead, Nov. 11 EDW. RAE

The Poles of Mars

PERMIT me through your columns to inquire whether any experiments have been made, by polarisation, to test the statement that the light from the brilliant spots round the poles of Mars is *reflected?*

If nothing has yet been done, will some correspondent decide the point? G. W.

Nov. 25

Lectures to Ladies

IN the fourth number of NATURE there is a letter signed "M." on this subject, in which it is asserted that nearly all the women who most wish to attend these lectures, and who would most benefit by doing so, "are practically shut out from those at South Kensington and at University College, because none of the lectures are given in the evening." Your correspondent gives South Kensington credit for saying something about "persons engaged in tuition," but she adds that it is a mere mockery, as this very fact prevents their getting out in the daytime.

I can confidently say that the Committee for the Higher Education of Women most earnestly desires to interest and benefit those who are teaching others, and who feel the necessity of a better education for themselves; but I believe that the wider and more general object of the whole movement (of which this small committee for South Kensington and Chelsea forms a struggling and isolated element) is, not *so much* to improve those who are already engaged in teaching, as to elevate the tone of education amongst girls who will eventually be teachers, whether as governesses or as mothers.

This I think is enough reason for giving the lectures in the daytime, for it would be difficult for girls to come out alone to classes in the evening. Of course it is hoped that in time a regular system may be established for the training of teachers and students at once, but meanwhile we can but trust that even these weak forces, if they are rightly directed, may have some good effect, if it is only in awakening an interest in these subjects amongst those who can help.

It is very difficult, in London especially, to get at the class of students which we most wish to benefit. I think the fact is that, in London at least, schoolmistresses and governesses are, with a few exceptions, inclined to be narrow and conservative on the subject of educational improvements. If they would only come forward and interest themselves in the scheme their co-operation would be most valuable.

I hope that your correspondent "M." and others who feel as she does, may see this letter and will understand how difficult it is at the outset to satisfy so many conflicting requirements at once.

The course of lectures on Greek History and Literature which Mr. W. R. Kennedy is now giving on Saturdays at the South Kensington Museum is very thinly attended, which is exceedingly discouraging, especially as particular pains have been taken to make these lectures strictly educational, by means of questions set to be worked at by the students at home.

Brompton, Nov. 30 M. A. B.

The American Eclipse

DR. MORTON, Professor of Chemistry in the University of Pennsylvania, has kindly forwarded me photographs of the phenomena of totality. By combining in the stereoscope pairs of these, separated by intervals of about half-a-minute of time, the black globe of the moon appears projected far in front of the luminous prominences and the corona, which are, therefore, clearly seen to belong to the sun. Glass transparencies from negatives specially selected for this purpose, and appropriately mounted, would show these phenomena in a very striking manner.

WILLIAM CROOKES

NOTES

TO-NIGHT the physicists take their turn at the Royal Society, and the physical constitution of the sun will form one of the subjects dealt with.

WE believe that the communication to be read at the Royal Geographical Society on Monday will be one of great interest.

A PERIODICAL, after the model of the popular *Annales des Sciences Naturelles*, will be commenced in Paris at the beginning of the year. It is to be named the *Annales des Sciences Geologiques*. We are promised an important and fully illustrated memoir on the Geology of Palestine, by M. Lartet. The editors of the new journal will be M. Alphonse Milne-Edwards for the Palæontological, and M. Hebert for the Geological departments.

THE Swedish Academy of Sciences has just issued, under the title "Lefnadsteckningar öfver Kongl. Svenska Vetenshaps Akademicus efter År 1854 aflidna Ledamöter," the first number of a series of biographical notices of those of its members who have died since the year 1854. In the absence of the preface, which is deferred until the publication of the second number, we are unable to say whether all the members of the Academy are thought worthy a special biography, or only its most distinguished members. However this may be, we fear that very few of the twenty men, whose lives are recorded in this first number, are known to fame beyond the limits of their native land, notwithstanding that most of them have left behind them honourable records of scientific labour. We do not say all of them, because we notice an archbishop and a bishop, whose claims to admission to the Academy must, judging from their published works, have rested upon their social position or general attainments rather than upon their scientific labours.

WE have been favoured by Professor Newton, of Yale College, with the following notes as to the November star-shower:—"We were unfortunate here this year in observations upon the November meteors. Both nights, the 13th-14th, and 14th-15th, having been overcast. Through breaks in the clouds we saw a few stragglers, some of which were true November meteors, radiating from Leo, and leaving for an instant the soft trail peculiar to those bodies. But the number of meteors during the hour between three and four a.m. of Monday morning was probably not more than double or treble the usual number for any morning. The small part of the sky visible prevented any reliable estimate of numbers. Similar weather has rendered observation impossible at every station from which I have heard."

FROM a preliminary report made to the Association Scientifique de France, by M. C. Wolf, of the Imperial Observatory of Paris.

we learn that the corps of observers appointed to watch the November star-shower was duly in the Marseilles district as previously arranged. On the night of the 12th, 210 stars were catalogued at Barcelonette, 116 at Marseilles, 120 at Montpellier, and only 31 at Orange (these last being merely sporadic). On the 13th, 130 stars were noticed at Orange. At this place the centre of the shower seems to have been much obscured by clouds, to the great disappointment of the observers. But elsewhere, especially at Turin, Marseilles, Valence, and Toulon, there was a magnificent display. The work of uniting the manifold results obtained, and deducing the distance of the bolides from the earth, as well as their radiant point, will shortly be commenced.

FATHER SECCHI writes to *Les Mondes* that the meteors of the 14th November were splendidly seen at Rome during half an hour when the sky was quite clear. Although this half-hour was not the time for the maximum display, no less than 183 meteors were observed. On the evening of the 13th, the meteors had already commenced to be visible in greater numbers than ordinary.

THE Rainfall Committee for 1860–69, in their report presented to the British Association at Exeter, remark that, as they are now on the eve of completing their decennial return for 1860-69, it behoves them to consider how they may best secure for the ensuing period the attainment of the objects for which they were originally constituted. They state that, even to those least acquainted with the subject, it will be apparent how much more desirable as well as easy it is to compare simultaneous observations than those wherein the observed values and their times are different. The number and distribution of the existing observation stations, though incomparably superior to that which existed some years since, is still capable of improvement; tracts of land, the rainfall of which as water-supply is of high importance, remaining without adequate observations, while other places are, if possible, too well provided. Mr. G. Symons requests us to announce that any persons who may be recording the fall of rain, or intending to record it, will oblige by forwarding to him, at 62, Camden Square, N.W., their names and addresses, in order that duplicate gauges may not be started unnecessarily near to them.

AT a recent meeting of the Ethnological Society some photographs of the great megalithic monuments in Wiltshire were exhibited. We understand that a scheme is now in progress to obtain funds for the purpose of procuring a series of photographic representations of the megalithic monuments found in England and France, and, if possible, in Europe and Algeria. Such a series, in which the compass-bearings and accurate dimensions would be given, would be invaluable to the student of archæology. Any of our readers interested in the work, who wish to know more of the details, are requested to communicate with the librarian, Royal Geographical Society, 15, Whitehall Place.

WE have been favoured by a correspondent with an account of a lecture given by Dr. Hector, at the New Zealand Institute, on the subject of Mining in New Zealand. The lecturer, in considering the mineral substances excavated from the superficial deposits, proceeded in the first place to give a short account of the building material. According to his statement, the number of building stones already worked in New Zealand is very large. They are generally divided into granites, limestones, and sandstones. There is a granite quarry at Adele Island, in Blind Bay; and the valuable stone also exists in unbounded quantities on the west coast of Otago, under circumstances most favourable for excavation and shipment. There is also very great variety in the colour and grain, whilst the quality is generally admitted to be excellent. Pure siliceous varieties of sandstones occur with the coal formations. The freestones are chiefly in the tertiary formation of New Zealand, from sandstone, to clay sandstones, and argillaceous sandy limestones, and pure limestone. The finest is the Oamaru stone, which, the lecturer stated, excelled most ordinary building stones in other parts of the world. There are no roofing-slate mines in New Zealand being worked, but there is no doubt that they exist. After reviewing the building materials, Dr. Hector passed on to the consideration of the valuable sands, the character and distribution of which were thoroughly explained.

WE have received the following note on the subject of the Holborn Valley Viaduct:—"From the position of the cracks in the columns it is evident that they have been bodily strained over towards the roadway. This may be accounted for by the great difference in weight between half the arch over the roadway and half the arch over the footway. Taking one girder and its load in each case, the weight of that over the roadway would be about eighty-five tons, and that over the footway only twenty-five tons; the additional weight over the column is eight tons, making therefore in all one hundred and eighteen tons supported by each column, and resting on a cap of the column which is five feet wide. Consequently, the centre of gravity of these weights is considerably out of the centre line of the column, and so tends to "cant" it over towards the roadway. Now, since a removal of the centre of pressure only one-sixth of the width of the cap from the centre line will double the strain on the edge nearest to the centre of pressure, the extra strain imposed on the side of the column nearest the roadway may be easily conceived. If in addition to this we assume the joints to be badly made (which appears probable), the cause of failure can no longer be a matter of surprise. For if the joints were made with convex faces no force would affect the outside filaments of the column, unless the whole column were crushed; but if concave, it is obvious that the edges would have to sustain the whole load. In the case of the Viaduct, as the load is unequally applied, the evil of the concave faces would be greatly exaggerated, and the column would necessarily be crushed on the faces nearest the roadway which support (as stated above) the greater weight. The report of the engineer may be shortly expected."

WE have received the following notes from our Dublin correspondent:—

Professor Jellett, B.D., has been almost unanimously elected as President of the Royal Irish Academy. One vote was recorded for Sir Robert Kane, F.R.S.

The Botanical Gardens at Glasnevin are known to the majority of the visitors to Dublin; they are beautifully situated on the banks of the little river Tolka, and contain a large collection of rare plants. Some years ago the Committee of Botany of the Royal Dublin Society, acting on the advice of the director of the gardens, purchased a large iron shed, in which they displayed portions of a collection of plants and their products useful to man. This structure was from the first quite unfit for preserving the valuable collection placed in it; the specimens were necessarily crowded together, and any arrangement was impossible. Still, the large numbers that visited this room to study the contents of the cases, and oftentimes to take notes of the history of the specimens, as told on their labels, testified to the great and intelligent interest that was taken in the collection by the public.

The special function of the Science and Art Department appears to be to provide for the improvement of the people in science and art, and they placed on the estimates for the four years between 1865 and 1869, a sum of 4,000*l.* for building a museum at the Botanical Gardens, close to the front entrance gate, through which so many thousand visitors pass in the course of each year. This sum, small though it may appear, would have been sufficient to have built and cased a large plain building, which would have contained all the present collection, and the additions to it, for many years; but though the money was voted by Parliament for several years, it was never applied to this purpose: and we think it but justice to the cause of science in Ireland, to call the attention of the Science and Art Department to this fact, and to urge them to have this sum inserted in the estimates for the coming year.

It is scarcely necessary to remind readers of NATURE of the importance of having the Museum of Economic Botany as close to the Botanical Gardens as possible, especially when, as in this case, these gardens are so largely resorted to; but it may not be amiss to inform them that the numerous members of the Royal Dublin Society have among themselves contributed, as donations, almost all the specimens in the present Economic Museum.

A local committee has been formed in Dublin of the "Veitch" Memorial. Dr. Moore, F.L.S., Director of the Botanical Gardens, Glasnevin, is the chairman, and a considerable number of subscriptions has been received.

AT a meeting of the Ashmolean Society, Oxford, Nov. 29th, Prof. Lawson read a short paper on Chlorophyll. Although he had made no original observations on this subject himself, he had no doubt but that a general view of what had been done recently by others would prove interesting to the Society. In speaking of the optical properties of chlorophyll, he called particular attention to the observations made on this branch of the subject by Professor Stokes; observations which had disproved the old theory that chlorophyll could be separated into two primary substances of a yellow and blue colour (the xanthophyll and cyanophyll of M. Frémy). He dwelt also upon the fact that Mr. H. L. Smith's careful comparison of the spectrum of the endochrom of diatoms with that of chlorophyll went far to prove the two substances to be identical. Chlorophyll had been formerly supposed to be a product of the vegetable kingdom only; but more recently a green colouring matter, closely allied to chlorophyll if not identical with it, had been detected in many of the lower forms of animal life. These discoveries illustrated in a striking manner how the supposed gaps between the two kingdoms were filled up.

AT Clare College, Cambridge, a scholarship, value 50*l*., tenable for three years, will be given for proficiency in natural science. The examination, commencing March 30, 1870, will be in chemistry, chemical physics, comparative anatomy, physiology, and geology. Excellence in one or two of these subjects is preferred to a less perfect acquaintance with a greater number. Further particulars can be obtained from the tutor of the college.

THE *Pall Mall* announces the publication of the seventeenth volume of the Report of the Schools Inquiry Commission. It comprises reports on the schools in what the Commissioners have defined as the north-western district—namely, the counties of Lancashire and Cheshire.

WE understand that it is not the intention of the Government to fill up the vacancy in the curatorship of the Botanic Gardens at the Mauritius, caused by the death of Dr. Meller, but to promote the head-gardener to the highest post of authority.

DR. McQUILLEN has exhibited in the Microscopical Department of the Academy of Natural Sciences at Philadelphia, slides of blood corpuscles of men and the lower animals, to which chloroform and nitrous oxide had been administered, to show that there was no morphological change in these bodies after administration of anæsthetics, as stated by certain physiologists in England. He showed specimens also in which, the blood corpuscles having been brought into actual contact with chloroform and ether, disintegration had taken place.

ON the same occasion, Mr. W. H. Walmsley called attention to the very great merits of glycerine jelly as a medium for the preservation of every description of objects, animal or vegetable. With this the most delicate tissues can be perfectly seen and examined; it preserves the colours, is very tenacious, and "its refractive powers are sufficient to render all inert structures transparent; while even the delicate lines on the scales of a mosquito's wing are as distinctly visible as if mounted dry." The formula for the preparation of this valuable jelly is thus set forth:—Take one package of Cox's gelatine, wash repeatedly in *cold* water, then place in a vessel and cover with *cold* water. Allow it to soak an hour or two, pour off superfluous water, add a pint of *boiling* water, place vessel on fire, and boil for ten or fifteen minutes; remove from fire, and when cool, but still fluid, add the white of an egg well beaten, replace on the fire, and boil until the albumen of the egg coagulates. Strain while hot through flannel, and add an equal portion by *measurement* of Bower's pure glycerine, and fifty drops of carbolic acid in solution: boil again for ten or fifteen minutes, and again strain through flannel; place in water bath, and evaporate to about one half; then filter (through cotton) into 2 oz. broad-mouthed phials. When thus made, the jelly is to be used in the mounting of objects as follows:—Place the stock bottle in a small jar of boiling water; when it becomes fluid, a sufficient quantity must be removed to the slide (previously warmed) with a glass rod; the object (previously soaked for some hours in equal parts of glycerine and distilled water, with a few drops of alcohol) is to be placed in the drop of fluid jelly, a cover applied, and a light weight placed upon it to exclude superfluous jelly. When cold, clean off the slide with a knife, wash in cold water, and finish with a ring of gold size or shellac varnish.

THE volume of the Memoirs of the Geological Survey of England and Wales, just published, consists of an important monograph on the Geology of the Carboniferous Limestone, Yordale Rocks, and Millstone Grit of North Derbyshire and the adjoining parts of Yorkshire, explanatory of sheets 81 N.E. and S.E., and 72 N.E. of the Survey Map. The work is by Messrs. A. H. Green, C. Le Neve Foster, and J. R. Dakyns; and contains an elaborate description of the geology of the district, illustrated with numerous important sections and a few views. Mr. Etheridge has contributed an Appendix and tabular list of fossils, with indications of the localities in which they occur.

ASTRONOMY

Spectroscopic Observations of the Sun

PROFESSOR C. A. Young, of Dartmouth, U.S., has communicated to the October number of the *Journal of the Franklin Institute* the following important observations of solar protuberances, which entirely endorse the work done by Mr. Lockyer in this country. We are enabled to place them thus early before our readers by the kindness of Professor Morton.

September 4th, 1869.—Prominences were noted on the sun's limb at 3 p.m. to-day in the following positions, angles reckoned from North point to the East:—

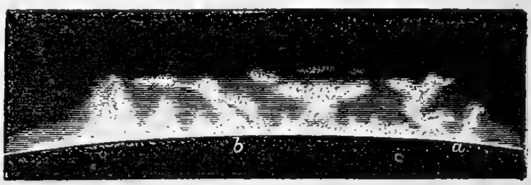


FIG. 1.

1. + 70° to + 100°, very straggling, not very bright.
2. − 10°, large and diffuse.
3. − 90°, small, but pretty bright.

September 13th, 1869.—The following protuberances were noted to-day.

1. Between + 80° and + 1100, a long straggling range of protuberances, whose form was as in Fig. 1. I dare not profess any

very extreme accuracy in the drawings, not being a practised draughtsman, but the sketch gives a very fair idea of the number, form, and arrangement of the immense cloudy mass, whose height was about 50″ and its length 330″ (22,500 miles by 1,350,000). The points *a* and *b* were very bright.

2. +135° small, but very bright at the base, of this form (Fig. 2).

3. −85° of this form (Fig. 3).

The dark spot, marked *c*, was very curious, reminding one strongly of the so-called fish-mouth in the nebula of Orion. I saw no change in it for 20 minutes. On the other hand, the first

Fig. 2.

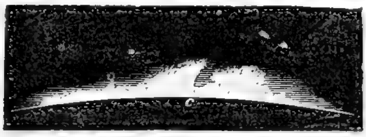

Fig. 3.

series mentioned were changing rapidly, so that at five o'clock the sketch which was drawn at two was quite inapplicable, only the general features remaining unaltered.

4. −128°, about 20″ high, forked, as in Fig. 4.

The structure was *cirrus* in every one but No. 3, which seemed more like a mass of cumulus.

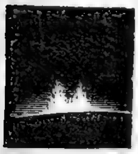

Fig. 4.

To-day, for the first time, I saw b_1 reversed in the chromosphere when the slit was tangent to disc; 1474 was easy; the new line at 2602 cannot be detected as yet.

At 2.25, while examining the spectrum of a large group of spots near the sun's western limb, my attention was drawn to a peculiar double *knobbishness* of the F line (on the sun's disc, not at the edge), represented by Fig. 5, *a*, at the point *e*. In a very few moments a brilliant spot replaced the knobs, not merely interrupting and reversing the dark line, but blazing like a star near the horizon, only with blue instead of red light; it remained for about two minutes, disappearing, unfortunately, while I was examining the sun's image upon the graduated screen at the slit, in order to fix its position, which was at −82½, about 43″ from the edge of the limb, about 15″ inside of the inner edge of the spot-cluster. I do not know, therefore, whether it disappeared instantaneously or gradually, but presume the latter. Fig. 5, *b*, attempts to give an idea of the appearance. When I returned to the eye-piece, I saw what is represented at Fig. 5, *c*, &c. On the upper (more refrangible) edge of F there seemed to hang a little black mote, making a *barb*, whose point reached nearly to the faint iron line just above F. As given on Angström's atlas, the wave-length of F is 486·07, while that of the iron line referred to is 485·92 (the units being millionths of a millimetre). This shows an absolute change of 0·15 in the wave-length, or a fraction of its whole amount, represented by the decimal 0·00030, and would indicate an advancing velocity of about 55·5 miles per second in the mass of hydrogen whose absorption produced this barbed displacement.

Fig. 5.

The barb continued visible for about five minutes, gradually resolving itself into three small lumps, one on the upper, and two on the lower line, Fig. 5, *d*. In about ten minutes more, the F line resumed its usual appearance. I did not examine the C line, as I did not wish to disturb the adjustments and risk losing some of the curious changes going on under my eye.

After the close of this strange phenomenon, I examined, with our large telescope of 6-inch aperture, the neighbourhood in which this took place, and found a very small spot exceedingly close to, if not actually *at*, the place. This was at 2.45. At 5.30 it had grown considerably.

Undoubtedly, the phenomenon seen was the same referred to by Mr. Lockyer when he speaks of often seeing the bright lines of the prominences not only at the sun's limb but on his disc. It is the only time I have had the good fortune to see it as yet.

GEOLOGY

Structure of Eophyton

THE *Geological Magazine* for the present month contains a paper by Mr. Henry Hicks, describing the structure of a fossil, from the Lower Arenig rocks of Ramsey Island, near St. David's, which he considers to be an *Eophyton*, resembling *E. Linnæanum* of Torell. The rocks in which this fossil occurs rest conformably upon Upper Lingula flags, and underlie rocks of the Skiddaw or Tremadoc series.

Mr. Hicks describes and figures the fossil under the name of *Eophyton* (?) *explanatum*. He describes it as a moderately convex stem, about four lines broad, jointed, and ribbed throughout its whole length. At one joint in the specimen described, the ribs bend outwards, as if to form a branch. The stem is covered by a very thin cortical substance, within which it is composed of minute tubular columns, lying close together, and running the whole length from one joint to another.

The *Geological Magazine* also contains papers by Mr. Ruskin on Banded and Brecciated Concretions, illustrated with a plate and several woodcuts; by Mr. Poulett Scrope, on the pretended raised Beaches of the Inland Slopes of England and Wales, severely criticising Mr. D. Mackintosh's recent volume on Geology and Scenery; by Prof. Harkness, on the middle *Pleistocene* deposits of Britain; by Mr. R. Tate, on additions to the list of British *Brachiopoda* of the secondary rocks, including a table showing the distribution of the British *Liassic Brachiopoda*; and by Mr. W. H. S. Westropp, on the occurrence of "albite" in the granite of Leinster. Lord Enniskillen contributes a catalogue of the type specimens of fossil fishes in his collection. The number also contains the usual notices, reviews, and abstracts of the proceedings of societies, correspondence, &c.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, December 2.—Dr. A. W. Williamson, F.R.S., in the chair. Sir Roderick Murchison, Bart., F.R.S., Messrs. M. H. Cochrane, Edward Smith, T. Walton, M.R.C.S., G. M. Hopwood, John Wiggin, Thomas Gibb, and George Harrison were elected Fellows. A paper on some points of the Chemical Nomenclature of Salts by Mr. H. G. Maden was read. The author advocated the use of the prefixes "proto" and "per" instead of the terminations "ous" and "ic" in the nomenclature of salts, and expressed his preference for the systematic names formed from English words, as "copper sulphate." Dr. Attfield recommended an adherence to trivial names like "calomel" and "corrosive sublimate," when possible, as changes in theory necessarily led to inconvenient alterations in nomenclature. Dr. Williamson objected to Mr. Maden's proposal to revert to the use of the prefixes "proto" and "per," on the ground that they had formerly produced great confusion, particularly in the nomenclature of the chlorides of mercury. He advocated an extension of the use of the terminations "ous" and "ic," which indicated the places of compounds in a series without binding chemists to particular views of constitution. He thought Mr. Maden's preference for English words might be carried too far and produce such terms as "brimstonic acid" and "charcoalic oxide." Mr. Vernon Harcourt expressed his general concurrence with the author. Dr. Odling pointed out that in certain names, such as "ferricyanide of iron," it was advantageous to use both English and Latin names. Dr. Voelcker thought that the employment of different names for the same substance familiarised chemists with different views of constitution. A communication from Mr. J. Hunter on the analyses of sea-water from different depths was read. The author gave the results of observations made during the recent scientific expedition of the *Porcupine*.

Zoological Society, November 25.—Mr. John Gould, F.R.S., V.P., in the chair.—Mr. Sclater made some remarks on the condition of various zoological gardens on the Continent recently visited by him, and on rare animals observed in those establishments. The secretary exhibited on behalf of Mr. John Brazier, C.M.Z.S., the eggs of a megapode (*Megapodius*) from Banks Island, New Hebrides, indicating the existence of a species of this genus in that group of islands. A letter was read from Mr. W. T. Fraser, C.M.Z.S., giving some confirmatory facts respecting the alleged existence of the rhinoceros in Borneo. Mr. R. B. Sharpe exhibited a specimen of *Alcedo grandis*, a rare species of kingfisher from the Terai of Darjeeling. Mr. Andrew Murray exhibited specimens of some articles of food sold in the markets of Old Calabar. These consisted of examples of a frugivorous bat (*Pteropus*) ready trussed, specimens of a rare crustacean (*Callianassa turnerana*), and the larvæ of a Longicorn beetle found in decayed palm-trees. A letter was read from Mr. E. L. Layard, of Cape Town, F.Z.S., containing some remarks as to priority of discovery of the remarkable nesting-habits of the hornbills. Mr. H. J. Elwes, F.Z.S., exhibited a fine pair of horns of the Sinaitic Ibex (*Capra nubiana*), and Mr. H. E. Dresser, F.Z.S., some eggs of the little gull (*Larus minutus*) recently taken in Russia. A communication was read from the Rev. O. P. Cambridge, containing notes on some spiders and scorpions recently collected in St. Helena by J. C. Melliss, Esq. Judging from this collection, which, however, was of small extent, the character of the *Araneidea* of St. Helena appeared to bear a thoroughly European stamp. A communication was read from Dr. O. Finsch, C.M.Z S., and Dr. G. Hartlaub, F.M.Z.S., on a small collection of birds recently received by the Museum Godefroyanum from the Tonga Islands. The species contained in this collection were eleven in number, one of which was believed to be new to science, and was proposed to be called *Myiolestes Heinei.* A communication was read from Surgeon Francis Day, F.Z.S., containing the second portion of his critical remarks on the fishes in the Calcutta Museum. Two papers were communicated by Mr. J. Brazier, C.M.Z.S., on the localities of certain species of land-shells and volutes found in Australia and the neighbouring islands, and on the species of cones met with in Port Jackson, N.S.W. Mr. R. B. Sharpe read a paper on the birds of Angola collected by J. J. Monteiro, Esq., which were accompanied by the notes of the collector. The present collection contained twenty-nine species, many of which were of great interest. A communication was read from Mr. D. G. Elliot, F.Z.S., containing a monograph of the genus *Pelecanus.* The species of pelicans recognised by Mr. Elliot were nine in number. Mr. Sclater exhibited a specimen of a new species of Mexican wren from the Berlin Museum, which he proposed to describe under the name of *Thryothorus nisorius.* Mr. Sclater also read some notes on the identification of two mammals recently described by Dr. Gray from specimens living in the Society's Gardens. A paper was read by Messrs. Sclater and Salvin on Peruvian birds collected by Mr. Whitely, being the fifth of a series of communications on this subject. Mr. John Gould, F.Z.S., exhibited and described a new species of kingfisher from North-Western Australia, which he proposed to call *Dacelo occidentalis.*

London Mathematical Society, November 25.—Prof. Hirst, and subsequently Prof. Sylvester, V.P., in the chair.—The Rev. James White was admitted into the Society, and the Rev. Percival Frost proposed for election. Dr. O. Henrici exhibited a model of the cubic surface $xyz - (\frac{3}{7})^3 (x + y + z - 1)^3 = O$, which has three biplanar nodes; it was constructed in cardboard to a scale of $2\frac{1}{2}$ inches, as unit. A sufficient number (eleven) of sections $x + y + z - 1 =$ constant, cut out in cardboard, are connected in a horizontal position, and kept at their proper distance by three vertical sections $y = z$, $z = x$, $x = y$, with regard to which the surface is symmetrical. The model contains the central part of the surface with the three nodes, and is bounded by a sphere of 8 inches radius, with its centre at the origin, large enough to show the position of the three straight lines in the surface (each counting for nine), and to give an idea how the surface extends to infinity. The interstices between the cardboard are intended to be filled up with plaster of Paris, so as to form a solid model. Mr. Clifford gave an account of an extension of a theorem of Serret's illustrated by tables, one of which, designated A, is annexed, with its explanation.

Power.	2	3	4	5	6	7	8	9	10
Conic	6	8	11	13	16	18	21	23	26
Cubic	—	10	12	15	19	21	24	28	30
Quartic	—	—	15	17	20	24	29	31	34
Quintic	—	—	—	21	23	26	30	35	41
Sextic	—	—	—	—	28	30	33	37	42
Septic	—	—	—	—	—	36	38	41	45
Octavic	—	—	—	—	—	—	45	47	50
Nonic	—	—	—	—	—	—	—	55	57

The tables, for convenience, refer to points instead of lines, and curves of given order instead of curves of given class. The meaning of them will best appear from an example. Thus, in the Table A above, opposite the word quartic and under the power 8 we find the number 29. This means that if the eighth powers of the equations of 29 points are connected by a syzygy, the points are all on a quartic curve. There are, moreover, intersections of the quartic by an octavic, which, in virtue of a theorem of Jacobi's, is an additional piece of information. Mr. Clifford also exhibited a second Table B, constructed in a similar manner for surfaces. Mr. Roberts made a statement of a theorem in invariants, which, however, is so mixed up with other considerations and details, that it cannot well be isolated and its limiting circumstances explained without going into further details than the limits of this notice permit.

EDINBURGH

Geological Society, December 2.—Mr. Geikie, F.R.S., president, in the chair. The first paper was on the Succession of the Laurentian, Cambrian, and Lower Silurian Rocks on the Shores of Loch Broom, being a letter addressed to the president by Sir Roderick Murchison.

Sir Roderick Murchison, in his paper, after alluding to his previous researches in Scottish geology, and especially to the order which he had been enabled to establish among the rocks of the north-west Highlands, proceeded to give the results of a visit which he had paid last summer to the west of Ross-shire. Along the shores of Loch Broom he found clear sections confirmatory of his previously published views. Among the Summer Isles at the mouth of that loch the Laurentian gneiss is found with its usual characteristic petrographical character. It throws off the dull red or chocolate-coloured sandstones which in one mountain, Ben More, must attain a thickness of several thousand feet. These strata are inclined gently towards the east, and are overlapped unconformably by the quartz rock and limestone which form the lowest portions of the Lower Silurian series. From the upper part of the uppermost quartz rock there is a perfect ascending passage with the upper flaggy gneiss, which rolls eastward over the rest of the Highlands. By this fresh appeal to the natural sections of the north-west Highlands, Sir Roderick had been again able to confirm the now established order of succession among these ancient rocks.—Mr. Geikie, F.R.S., afterwards communicated a series of notes for a comparison of the volcanic geology of central Scotland with that of Auvergne and the Eifel. The author began by alluding to the labours of Boué, Forbes, Scrope, Daubeny, and others. He then sketched the area occupied by rocks of volcanic origin between the Grampians and the silurian uplands of the southern counties. The rocks which he proposed to make the subject of more special remark in this paper were of carboniferous age.

They were capable, he said, of being broadly treated under two groups—1st, plateaux; and 2d, points of local eruption. 1. Plateaux of carboniferous volcanic rocks are extensively developed in the western part of the midland valley. They form the range of the Campsie and Kilpatrick fells, and, crossing the Clyde into Renfrewshire, sweep for many miles through the north and north-east of Ayrshire. They occur likewise as fragments on the Clyde islands, Arran, Bute, and Cumbrae. Extensive as the present area of these rocks is, there can be no doubt that it once covered a much greater surface, and that one great plateau of lavas and tuffs stretched from the Ochil Hills to the south of Cantyre. Throughout the wide district where the rocks still remain they retain a remarkable horizontality. They consist of various porphyrites, melaphyres, and tuffs, arranged in beds, which are placed over each other with great regularity. Hence the hillsides wear a terraced appearance from the alternation of harder and softer beds. This feature characterises the Campsie fells and the hills south-westwards to Ardrossan, but it is most conspicuously displayed in some of the valleys at the south end of Bute. One of the distinguishing features of these plateaux is the comparative infrequency with which any vent or true point of eruption can now be detected. Occasionally such a vent is found as a boss of coarse volcanic agglomerate, or of porphyrite or melaphyre; but, as a rule, all the foci of eruption are now buried under the materials which they emitted. Another feature which runs through the plateaux is the apparent continuity of the several beds. Viewed from a little distance, the terraces of trap seem each perfectly continuous for long distances. A closer examination often shows that though the terrace may run on, the rock of which it consists is formed of different sheets, which, though lying on the same plane, have proceeded from different vents. Mr. Geikie then pointed out the structure of some of the volcanic plateaux of central France as illustrative of those features of the Scottish plateaux to which he had referred. (2) While the western half of the Scottish carboniferous area is characterised by the wide extent of its volcanic plateaux, the eastern half is as strikingly distinguished by the abundance of its points of local eruption. Traces of these independent but closely segregated vents are scattered over almost the whole extent of Fife and the Lothians. They belong as a whole to the lower division of the carboniferous formation. The evidence by which their position can now be ascertained consists of masses of stratified tuff, frequently associated with contemporaneous outflows of melaphyre. The number of the vents in some parts of the country must have been very great. During the deposition of the lower carboniferous rocks, the area of Linlithgowshire and great part of Fife and East Lothian was dotted over with little volcanoes, each throwing up its cone of ash, or here and there emitting also a short current of lava. In some places the vents were so closely placed together, that their ejections formed in the end one long volcanic bank, such as the Garlton Hills and the range of heights between Bathgate and Linlithgow. The vents were singularly local in their development. Thus, while they continued in activity throughout Linlithgowshire and Fife, as well as in Haddingtonshire, the intervening area of Edinburghshire remained almost without them. Their long continuance in the districts where they had once broken out is remarkable. During the time represented by the deposition of many hundred feet of strata, the area of Linlithgowshire continued to be the theatre of a wonderful volcanic activity, new cones breaking out as the old ones were washed down. Yet the county of Edinburgh, only a few miles to the east, remained during that long period almost wholly unaffected by any volcanic action. Reference was then made at some length to the extinct volcanoes of Auvergne and the Eifel, and it was shown that in their form and distribution, their small size, the nature of their products, and the protracted period during which they had been in activity, they enable us to realise vividly what was the condition of a great part of central Scotland during the earlier ages of the carboniferous period. The concluding portion of the paper dwelt upon the denudation of the volcanic rocks of Auvergne and of Scotland. Mr. Scrope had shown conclusively that the wide and deep valleys of the Loire, the Dordogne, and other streams of central France had been carved out of volcanic rocks and fresh-water strata by subaërial erosion alone. The form and structure of these valleys were compared with those of valleys which have been excavated out of volcanic rocks in Scotland, and it was argued that the similarity of result was in all probability due to a similarity of cause. In the Scottish valleys the influence of ice, and perhaps, in some cases, also of the sea, had come into play to augment or modify that of the subaërial forces. Yet there was every reason to believe that in Scotland, as in France, the main share of the work had been done by rains, frosts, and streams.

DUBLIN

Royal Irish Academy, November 30.—The Earl of Dunraven, F.R.S., V.P., in the chair. The minutes of the former meeting, having been read and approved of, were signed. The chairman briefly expressed his regret and that of the Academy at the resignation of their former president, Lord Talbot de Malahide, and stated that he was ready to receive the names of any candidates for the vacant office. The Rev. Dr. Lloyd, F.R.S., Provost of Trinity College, proposed that Professor Jellett should be elected president. Among all the members of the Academy he knew of none save one (Rev. Dr. Salmon, F.R.S.), who, in his opinion, from his great scientific attainments, was so eligible for this important post; and his friend Dr. Salmon had announced his determination to withdraw his claims in favour of Mr. Jellett's. Mr. Jellett was distinguished not only for his knowledge of the higher branches of mathematics, but also for his knowledge of their application, a combination not often to be met with in the same individual. He felt sure that Mr. Jellett's presidency would be as distinguished as that of any of his predecessors. Dr. Stokes, F.R.S. (in the absence of the Rev. Dr. Russell, President of the Royal College of Maynooth), seconded Mr. Jellett's nomination. He reminded the Academy of the importance of having for its president one who was well versed in its affairs, and Mr. Jellett, when secretary of the council of the Academy, had acquired this knowledge. He would not refer to Mr. Jellett's position as a man of science, but he would remind that large and influential section of the Academy, the antiquaries, how much assistance they could have, and were constantly having, from science. Archæology was intimately connected with the natural sciences. Even the laws relating to the flow and ebb of the tides were shown by Professor Haughton to be thus connected, for he had calculated the hour of low tide in the Bay of Dublin on the day of the battle of Clontarf, and his hour absolutely coincides with that named in the written record as translated by the late lamented Dr. Todd. Sir William Wilde said that the provost had spoken of Mr. Jellett's position as a man of science, and Dr. Stokes had spoken of his general attainments and knowledge of the Academy's affairs; but he wished to speak of him as a colleague with whom he had been associated for many years, and as an honest, straightforward man, who, irrespective of all party feeling, did what he considered right without fear, prejudice, or favour. The Academy had had "antiquarian" presidents; it was now time to have one scientific president, and so win back many scientific wanderers. He felt sure Mr. Jellett would never forget the interests of the antiquarian party in the Academy, and he looked forward to a bright career for the Academy under Professor Jellett. Dr. Stewart, as a very old member of the Academy, supported Mr. Jellett's claims. There being no other candidate proposed, the ballot was opened and scrutineers appointed. The chairman announced that there appeared, for Professor Jellett, 55 votes; for Sir R. Kane, 1. He therefore declared Mr. Jellett duly elected as president. The chairman then, with a few graceful remarks, in which he congratulated the Academy on its choice, resigned the chair to the new president.—Sir W. Wilde exhibited a number of antiquities found in the counties of Dublin, Londonderry, and Queen's County, among which were a spirally twisted gold torque, either used as a finger ring or a head ornament, three bronze mammillary brooches, some fragments of bronze rings and bracelets, and a semicircular brooch of beautiful decoration and unique form. The remainder of the collection was chiefly of iron, and consisted of three very fine swords with hilts. Sir William also exhibited a collection of antiquities and casts from North and South America.—Professor Apjohn, M.D., read a paper "On a new step in the analysis of sugar." He stated that crude sugar and syrups generally contained three varieties of saccharine matter, and in the case of such a mixture, the method hitherto in use only accomplished the estimation of one of these, that usually known under the name of Cane Sugar. The means of obtaining its amount, by the optical saccharometer alone, or by Barreswil's solution, each being applied before or after conversion, he then briefly explained, pointing out at the same time that neither the optical nor the chemical method could give any information in relation to the amount of inverted sugar or of grape sugar (crystallised glucose) which might happen to be present. This problem, however, he thought could be completely solved by a combination of the processes adverted to, and this he demonstrated by drawing attention to two equations—the one expressing the result of an observation with the saccharometer, the other that obtained by operating on the solution of copper with the syrup both before and after its inversion. These equations involved three unknown quantities, but one of the three (the cane) might be determined by a preliminary observation with the saccharometer, and as by this contrivance the number of unknown quantities would be reduced to two, the problem admitted of a complete solution. This method of analysis he had recently applied to several saccharine substances, and with satisfactory results.

Royal Geological Society, November 10. — Dr. W. Stokes, F.R.S., in the chair.—Rev. Professor Haughton read a paper on the discovery of crystals of Albite in the Dalkley granite; the mineral was found by Mr. W. H. S. Westropp, in small crystals mixed with crystals of fluorspar. The existence of this felspar in the Leinster granite was predicted by Professor Haughton some years since, but it had not been found in a separate crystalline form until these specimens were discovered. This fact adds a new link to the chain of observations made by Professor Haughton relative to the classification and origin of granites, and shows the connection between the three great granite masses of Mourne, Leinster, and Cornwall, in all of which now the presence of albite has been distinctly ascertained. —Dr. Macalister exhibited some human and canine bones brought by Mr. H. Ormsby, Esq., Geological Survey, India, from the celebrated cave Uaimh Fraing, Island of Eigg, the remains of some of the Macdonald clan, who were smothered there in the sixteenth century.—Dr. Foot exhibited human bones from the cave of Dunmore, county Waterford, the remains of an Irish tribe suffocated there in the tenth century.—Specimens of the gold-bearing quartz of South Australia were sent for exhibition by Mrs. Gray, of Nareebnareeb, and of the gold-bearing quartz of the Rocky Mountains by Dr. Trevor, of Mentena.—Mr. Harte, County Surveyor of Donegal, exhibited some specimens of polished red granite from that county, which were of great beauty, similar in appearance to that of Peterhead, Aberdeenshire.

Natural History Society, December 1.—Mr. W. Andrews, V.P., in the chair. Dr. A. W. Foot read a paper entitled "Notes on Irish Lepidoptera collected during the past summer." These notes were chiefly records of a pleasant summer's excursion in which no very great rarities were met with. *Colias edusa* was found abundant in the County Kilkenny, and *Vanessa polychloros* was mentioned on the authority of a friend as having been seen in the County Wicklow. Mr. Williams, Mr. F. W. Kirby, Mr. Montgomery, and Dr. Haughton made remarks on the interest of many of the facts recorded in these notes. Mr. W. Andrews, the chairman, stated that it was a mistake to call *Chrysophanus dispar* the scarce copper; that *C. virgaureæ* was the scarce copper. He asserted that *C. dispar* was not rare in England, and that he had met with it in Kerry. He also said that the *Limenitis* which he had exhibited some years ago as from Tarbert, was neither *L. sibilla* nor *L. camilla*, but something quite different from either; and that those who thought it was *L. camilla* were quite wrong. He said he would bring all these facts before the society at another time. [Perhaps some of our entomological readers will enlighten us on these points. Is it possible that *C. dispar* is not a scarce butterfly? Is not *C. virgaureæ* a continental insect? If the *Limenitis* referred to is not, as competent authorities assert, the *L. camilla* of the Continent, what species is it?]

Newcastle-upon-Tyne

Chemical Society, October 28. Annual Meeting.—Mr. I. Lowthian Bell, F.C.S., President, in the chair. After the transaction of the business of the Society, the President read his address, in which he referred to the more important subjects which had engaged the attention of the Society at the evening meetings. He dwelt at length upon Mr. Pattinson's paper on the relations between English and Foreign Alkalimetry and Chlorimetry, which pointed out the fallacious results arising from the retaining of the old atomic weight of soda. He also called attention to the importance of Mr. B. S. Proctor's paper on the Root of the Rhubarb Plant, which exposed the fallacy which had led druggists and the medical profession, for the sake of mere appearance, to reject the portion of the drug richest in the active principle. The following extract from the address, alluding to the relations of science to the public health, is particularly interesting:—"Among the manifold applications of the truths revealed by means of chemical research, there is none more gratifying to the philosopher or to the philanthropist than that whereby chemistry is rendered subservient to the protection and promotion of the public health. It has been reserved almost for our own time to have it demonstrated that the observance of certain so-called sanitary regulations is connected by the closest bonds with the rate of mortality. This has been proved repeatedly in several large cities, at one time conspicuous for the high annual death-rate among their inhabitants, but which, by the authorities dealing with the causes of offence, now escape from the penalty which never fails to attend on the transgression of any great natural law. We need not, indeed, go far for an example in illustration of the doctrine I am enforcing, for in the very town in which we are now assembled, the rapid increase of population had outgrown as it were some of those means and appliances which must accompany the crowding together of a vast number of human beings on a small area of ground. The municipal authorities of Newcastle were no sooner properly impressed with the gravity of their position, and convinced that the remedy and responsibility rested in their own hands, than the most vigorous measures were resorted to in order to grapple with the evil, and we have, in consequence, to congratulate ourselves on a remarkable alteration in the death-rate of this town. It may not be unworthy of mention that the first quarter of 1866 exhibited a mortality corresponding to 48·4 for every thousand of the inhabitants, and that the average for the whole of that year was a mere fraction within 40, viz., 39·7. Taking 10 years, ending with 1860, it was 35·4 per 1000. It cannot be otherwise than satisfactory to compare this with the three quarters of the present year, which is only 26·2, and for the last quarter the deaths only amounted to 23·3 per 1000; in short, from having held a most unenviable position among the most unhealthy towns of the empire, we are now conspicuous among those in which the mortality is the lowest. I am glad to be able to state that the condition of our atmosphere, as affected by the burning of coal and the emission of objectionable vapours, is now engaging the attention of a Committee, with the Mayor at its head, appointed to inquire into the subject. I trust, now that the public mind has been directed to the evil of a smoke-obscured sky, or poisoned air, before long, the inhabitants will experience a happy change from the result of the labours of those charged with the investigation. It is only, however, due to our chemical manufacturers to state that they are fully alive to the importance of not permitting any unnecessary escape of vapours, having an actual value to themselves, and very inconvenient to others when set at large, and therefore, that they do not intend to rest content with the occasional visit of the Government inspector, or of their own superintendents, but are making arrangements for the permanent and continuous sampling of the gases after they have passed their condensing apparatus. Their observations in this direction, will, I feel assured, be much lightened by a very ingenious aspirator, constructed by one of our members, Mr. Swan, now on the table, to which I would invite inspection. I have, myself, been engaged for some time in an examination of the state of combustion experienced by the fuel in our blast-furnaces, and I am so satisfied that a proper study of the phenomena attending it involves considerations of the utmost importance to the iron-smelter, that I intend availing myself largely of the facilities which the apparatus of Mr. Swan is capable of affording." The officers of last year were re-elected by a large majority.

Norwich

Geological Society, November 11, Anniversary Meeting.—The Rev. John Gunn, F.G.S., President, in the Chair. The President and Hon. Secretaries (Mr. J. E. Taylor, F.G.S., and Mr. John King) were re-elected. In his opening address Mr. Gunn alluded to the death of one of the hon. members of the Society, Mr. Bernard B. Woodward. Referring to a paper by Mr. Harmer, F.G.S., on the Chillesford clay and the crag containing *Tellina balthica*, he stated that he had himself published a diagram of the coast and inland sections of Norfolk, and a description of what seemed to him a downthrow of Chillesford clay, or an upthrow of the chalk. He had also instituted a series of measurements of the various levels at which this bed appeared above the water, with a view to determining the amount of disturbance, and had found the heights ranging from fourteen to thirty-two feet. He thought that the difference between the coast and inland sections might be due to this disturbance. Mr. Gunn then noticed an excursion which had been made by the Society to Aldborough, where the Norwich crag had been found near the railway station, associated with undoubted red crag forms. He also adverted to the paper by Mr. Tylor (read before the Geological Society of London) on Valley Gravels. In the discussion which followed the President's remarks, Mr. Harmer gave an outline of the theory he had put forth in his Paper with reference to the bed of shells containing *Tellina balthica*. Both he and Mr. Searles Wood held this to be the base of the lower drift beds, and contended that a great change in the physical geography of the Eastern counties had taken place between the period when the upper and lower Norwich crags had been formed, and the time when the *Tellina balthica* bed had been deposited. The former had been deposited in an estuary opening to the south, the latter in a similar one opening to the north. This argued an oscillation of level in the meantime. Mr. Harmer also expressed himself against the theory that so-called valley gravels were of fluviatile origin, and pointed to Lopham Ford, where the height of the ground was only twenty feet above water level; and yet which was the point of departure for two streams whose much higher banks at some distance were covered with valley gravels containing flint implements. With regard to the opinion that many of the flint implements had been rolled down or transferred to the lower levels, Mr. J. E. Taylor stated that at Sainton Downham these implements were found in their most perfect and totally unaltered condition at the lowest levels. The chippings and edges were as fresh as when the weapons left the hands of their makers. He suggested that the vicinity of Lopham Ford might have been denuded by atmospherical action since the origin of the present rivers. Mr. Taylor then gave an account of a recent visit to Chillesford, in Suffolk, where he had studied the typical section, and taken an inventory of the commonest fossils and their mode of occurrence. The crag intercalated between the Chillesford clay contained great quantities of *Mactra solida*. This was the shell found so abundantly at Arminghall, near Norwich, in a bed resting on a portion of the Chillesford clay. The usual beds which, in the neighbourhood of Norwich, were found underlying this clay, were absent at Arminghall, so that the clay rested on the solid chalk. He had no doubt, therefore, that the intercalated crag at Chillesford was represented at Arminghall by the *Mactra solida* bed.

Paris

Academy of Sciences, November 29.—The following mathematical papers were read:—On a potential of the second kind which solves the equation with partial differences of the fourth order, expressing the interior Equilibrium of elastic, amorphous, non-isotropic substances, by M. de Saint-Venant, and a note on a certain class of differential equations of the second order by M. Laguerre. A note found among the papers of the late M. Léon Foucault on the construction of the optical plane was read. It gave a description of the method adopted by M. Foucault to obtain a perfectly plane surface of glass, and was supplemented by some remarks of M. A. Martin on his experience in the employment of the same method.—M. P. Gervais presented a note accompanying preparations relating to the anatomy of the Great Anteater.—M. Melsens communicated a memoir on the Passage of Projectiles through Resisting Media, in which he treats of the conveyance of air by projectiles moving through it, and the effect of the compression of the air upon the course of the projectile.—M. Scoutetten presented a note on the Preservation and Improvement of Wines by Means of Electricity. He stated that by the application of a current of electricity generated by a battery, and passed into the wine by means of platinum electrodes, its quality is greatly improved.—M. A. Gerardin remarked upon the unhealthy conditions produced by the discharge of the water of starch manufactories into rivers, and maintained that he had restored some rivers into a healthy condition by causing the water containing albuminous and other organic refuse to be discharged upon well-drained arable land. A paper on a very simple system of floodgates with a constant yield under variable pressure, by M. Maurice Lévy, was communicated, as also a note by the same author on a peculiar system of skew-bridges. MM. P. Desains and E. Branly communicated some investigations on solar radiation. They have found that the calorific action of the sun increases in intensity with the altitude of the place of observation, but that the transmissibility of the rays through water diminishes with the altitude. The transmissibility of the solar heat through water and alum was found to be greater in the morning than at noon, but this was not so strikingly the case in October as in August. The authors stated that their spectroscopic observations were in accordance with the preceding results. A paper by M. J. Moutier on the expansion of gases was presented, as also a note on molecular actions in chlorine, bromine, and iodine, by M. C. A. Valson. In the latter the author described his experiments to ascertain the amount of molecular action in chlorine, bromine, and iodine, by determining the height to which solutions of precisely equivalent quantities of their salts would rise by capillary action. From his results he inferred that if chlorine and iodine could easily be brought into a liquid state, the capillary elevations of the three bodies above-mentioned in a tube 1 millimetre in diameter would be respectively 6, 5·5, and 5 millimetres. The author suggested that the capillarity of substances may be made available in chemical analysis, and remarked that in its physical properties bromine stands nearly midway between chlorine and iodine. MM. Odet and Vignon presented an account of a new method of preparing anhydrous nitric acid, founded upon that proposed by Gerhardt for obtaining the anhydrous monobasic organic acids. They prepared chloride of azotyle by the action of oxychloride of phosphorus upon nitrate of lead or silver. The vapours of this chloride of azotyle were directed upon dry crystals of nitrate of silver at a temperature of 140°—158° F; the products of the reaction were conveyed into a tube immersed in a mixture of ice and common salt, where they furnished colourless prismatic needles presenting all the properties described by H. Sainte-Claire Deville. The authors described a simplified form of apparatus in which the acid may be produced without the preliminary preparation of chloride of azotyle, and indicated the reactions which take place. M. J. Roussin communicated a paper on the preparation of hydrate of chloral and on its characters when pure. His process consisted in submitting the crude crystalline mass obtained by passing dry chlorine through absolute alcohol to strong pressure until it is quite dry, then placing it in a retort with a little powdered chalk and distilling it. M. Dubrunfaut presented a paper on inverted sugar, in which he declared the results lately communicated to the Academy by M. Mauméné to be erroneous.—A memoir by M. E. Van Beneden on the mode of formation of the ovum and the embryonic development of the *Sacculinæ* was read; to this we shall probably advert elsewhere.—M. Marié-Davy presented a third note on lunar radiation, containing the results of his observations on this subject during the month of November. The following papers were also communicated:—On a new means of diagnosis and extraction of iron projectiles and leaden projectiles with an iron nucleus, by M. Milliot; on a new electrical explorer for detecting foreign (especially metallic) substances in the tissues of the human body, by M. Trouvé; on a system of aërial navigation (title only), by M. A. Vaillant; a description of clinical experiments upon the therapeutic effects of bromide of morphine and atropine, and bromide of digitaline (title only), and an indication of a mode of curing stings by cauterisation (by the use of phenic and sulphuric acids), by M. Delagrée; and a note on the supposed influence of subterranean marshes in the development of intermittent fevers, by M. Colin.

Berlin

Academy of Sciences, October 11.—Professor Magnus read a paper on the alteration of the radiation of heat by roughening of the radiating surface, in which he described a series of experiments made by him to determine the cause of this alteration, and stated that in his opinion the increased radiation of a roughened surface depends essentially upon the refraction which the heat undergoes in issuing from the surface of the radiating body. —Professor W. Peters communicated a notice of a new species of Lizard, *Phyllodactylus galapagensis*, from the Galapagos Islands. He remarked that only five species of reptiles were previously known from these islands—one tortoise, three lizards, and one snake. The last he identified with *Dromicus chamissonis*, which also occurs on the continent of America, and with this Dr. Günther's *Herpetodryas biserialis*, from the Galapagos group, may be synonymous. If it be distinct, the number of reptiles from these islands will only be seven.—Prof. Pringsheim read an elaborate memoir on the conjugation of swann-spores, the morphological primary form of reproduction in the vegetable kingdom, and a communication was presented by Dr. K. Schultz-Sellack on the diathermancy of a series of substances for dark heat. The author stated that he had found that many more substances than is generally supposed allow a considerable amount of the dark heat radiated by lampblack at 212° F. to pass through them. He enumerates binary compounds of chlorine, bromine, fluorine, and iodine, and a number of sulphides, and shows their behaviour in this respect by means of percentage tables.

German Chemical Society, November 12.—The following papers were read:—Otto on Mercuric Phenylide.—Kolbe: Lecture Experiment to demonstrate the increase of weight of burning substances.—Kempf on Carbonate of Phenyl.—Carstanjen on the Action of Oxychloride of Chromium on Hydrocarbons.—Henry on Chlorosulphide of Phosphorus.—Radizewsky on the Wax contained in the Straw of Cereals.—A. W. Hofmann on the Action of Iodine on Thiobenzamide.—Friedel: Paris Correspondence.—Richter: Petersburg Correspondence.

Bonn

Natural History Society of Rhenish Prussia and Westphalia.—The autumnal gathering of this society took place on the 11th October, the day so widely observed as the centenary of the birth of Humboldt; and the proceedings were naturally inaugurated by a discourse in commemoration of the great philosopher of whom the Germans are so justly proud. The following are the more important communications submitted to the society:—The veteran Prof. Nöggerath gave an account of the earthquakes, four in number, which since November 1868 have visited the Rhine province, specifying the extent of country subject to their influence, and glancing at the general physical characters of earthquake phenomena. He was followed by Prof. Troschel, who showed the importance of a study of the geographical distribution of animals as indicating the configuration of the earth's surface, and the distribution of land and water at the time of the commencement of the existing period of geological history. The Professor's illustrations were chiefly derived from his investigations of the distribution of sea-fish and land-snails. Professor F. Zirkel, of Kiel, made some communications on the mineralogical constitution of the basalt-lavas of Laacher See and the Eifel. Professor von Rath described a new mineral from Laacher See, which he proposes to call Amblystegite, in allusion to the extreme obtuseness of some of its angles. It is of a reddish brown colour; hardness almost equal to that of quartz; specific gravity 3·454; melts with great difficulty, forming a black glass insoluble in hydrochloric acid. In composition it is allied to hypersthene, but is distinguished from that mineral by the absence of the characteristic cleavage. Extracts from a paper by Professor Fuhlrott on the caves of Grevenbrück and the Hönnethal were then read; and Professor Schaffhausen availed himself of the opportunity of insisting upon the desirableness of a systematic exploration of the bone-yielding caves in which Westphalia is so rich. We are glad to hear that steps are being taken to raise funds for this purpose among the members of the society. The most important finds in the Grevenbrück cave are coprolites of hyæna, and two human lower jaws of primitive form.

Vienna

Imperial Academy of Sciences, November 18.—Professor Unger communicated a memoir on the anthracite deposits in Carinthia. He stated that nineteen species of plants, chiefly ferns, have been detected in the shales accompanying this deposit. They agree with those of the coal-measures, and eight of them occur also in the anthracite deposits of Styria, Switzerland, and the French Alps. Two undescribed Fern-stems were particularly noticed by the author, who took the opportunity of opposing the ordinary notion that the *Stigmariæ* are the roots of *Sigillariæ*. Of the latter he regarded those species which have not furrowed stems, as ferns.—Dr. C. Jelinek presented a preliminary communication upon the hurricane-like storm which visited Vienna on the 14th November. The greatest velocity of the wind was 46·6 Paris feet per second, about noon; the diminution of barometric pressure continued until 6 P.M., when the mercury had fallen 7·17 lines, the velocity of the wind being 36·5 feet per second.—Director Tschermak communicated a memoir on a new salt from Hallstadt. This mineral, to which the author gives the name of Astrakanite, occurs mixed with common salt, anhydrite, and a mixture consisting chiefly of sodium sulphate in the Christina gallery at Hallstadt. It forms a bluish layer, the colour being due to enclosures containing iron, and the crystals, which are very small and occur in druses, being frequently colourless. Its composition is expressed by the formula, $MgSO_4$, Na_2SO_4, 4aq, so that it is the third natural magnesium-sodium sulphate with which we are acquainted. M. Tschermak also presented a paper by M. P. Hausenschild, giving an account of his microscopic examination of the minerals called Predazzite and Pencatite. By the examination of thin slices of the most homogeneous looking specimens, the author found that two minerals may be distinguished in them with certainty, namely, calcite and brucite.—Dr. Samuel Stern presented a memoir entitled "Contributions to the theory of ordinary (not musical) sounds, as an objective character, with reference to the special requirements of medical diagnosis."—Prof. E. Ludwig presented a paper by himself and Dr. J. Hein upon the synthesis of hydroxylamine, which, they said, may be effected by the direct addition of nascent hydrogen to pure nitrous oxide as follows:—

$$NO + H^3 = NH^3O.$$

The process consists in passing nitrous oxide through a mixture of tin and hydrochloric acid, freeing the fluid from tin by sulphuretted hydrogen, evaporating the filtrate from the sulphuret of tin to dryness, washing the residue in cold and dissolving it in hot alcohol, separating the ammonium chloride with platinum chloride, and precipitating the pure hydrochlorate of hydroxylamine by anhydrous ether. The analysis and measurement of the crystals thus obtained proved their identity with Lossen's salt.—The following memoirs were presented, but only their titles are given: By Prof. Hyrtl, "On a præcorneal vascular net in the human eye," and "On an insular intercalated bone in the parietal bone;" and by Prof. B. Lapschin, of Odessa, "On the specific gravity of the water of the Black Sea," and "On the conductibility of cork for heat, and its application to the construction of a barometer." Prof. Julius Wiesner also presented a memoir on the origin and increase of Bactria, the results of which had been communicated to the Academy on the 29th April last.

DIARY

THURSDAY, December 9.

Royal Society, at 8.30.—Spectroscopic Observations of the Sun, No. V.: Mr J. Norman Lockyer, F.R.S.—Researches on Gaseous Spectra in relation to the Physical Constitution of the Sun, Note III.: Dr. Frankland, F.R.S., and Mr. J. Norman Lockyer, F.R.S.—On the Successive Action of Sodium and Iodide of Ethyl on Acetic Ether: Mr. J. A. Wanklyn.

Society of Antiquaries, at 8.30.—On a Faliscan Inscription: Padre Garrucci, Hon. F.S.A.

DARWINISM AND NATIONAL LIFE

THE Darwinian theory has a practical side of infinite importance, which has not, I think, been sufficiently considered. The process of natural selection among wild animals is of necessity extremely slow. Starting with the assumption (now no longer a mere assumption) that the creature best adapted to its local conditions must prevail over others in the struggle for existence, the final establishment of the superior type is dependent at each step upon three accidents—first, the accident of an individual sort or variety better adapted to the surrounding conditions than the then prevailing type; secondly, the accident that this superior animal escapes destruction before it has had time to transmit its qualities; and, thirdly, the accident that it breeds with another specimen good enough not to neutralise the superior qualities of its mate. In the case of domesticated animals the progress is incomparably more rapid, because it is practicable, first, to modify the conditions of life, so as to encourage the appearance of an improved specimen; next, to cherish and protect it against disaster; and, lastly, to give it a consort not altogether unworthy of the honour of reproducing its qualities. The case of man is intermediate in rapidity of progress to the other two. The development of improved qualities cannot be insured by judicious mating, because as a rule human beings are capricious enough to marry without first laying a case for opinion before Mr. Darwin. Neither would it be easy, nor, perhaps, even allowable, to extend any special protection by law or custom to those who may be physically and intellectually the finest examples of our race. Still, two things may be done: we may vary the circumstance of life by judicious legislation, and still more easily by judicious non-legislation, so as to multiply the conditions favourable to the development of a higher type; and by the same means we may also encourage, or at least abstain from discouraging, the perpetuation of the species by the most exalted individuals for the time being to be found. Parliament, being an assembly about as devoid of any scientific insight as a body of educated men could possibly be, has not as yet consciously legislated with a view to the improvement of the English type of character. Without knowing it, however, the Legislature has sometimes stumbled on the right course, though it has more often blundered into the wrong. Our free trade policy has furnished special scope and special advantages to the energetic enterprising character, and so far has tended to perpetuate and intensify the type which has given to little England her wonderful prominence in the world. On the other hand, the steady refusal to make a career for scientific men has drained away most of our highest intellect from its proper field, and has subjected the rest to an amount of discouragement by no means favourable to increase and improvement. Our laws and customs practically check the growth of the scientific mind as much as they tend to develop the speculative and energetic commercial character.

We do not expect for a long time to hear an orator in the House of Commons commence his speech by announcing, (as a distinguished member of the Austrian Reichsrath recently did, in a debate on the relation of the different nationalities in the empire), that the whole question is whether we are prepared to accept and act upon the Darwinian theory. But even an average English M.P. may be brought to see that it may be possible, indirectly, to influence the character and prosperity of our descendants by present legislation, and none will deny that, if this is practicable, a higher duty could not be cast upon those who guide the destinies of a nation.

A glance at the operation of Darwinism in the past, will best show how potent it may be made in the future. Look at English progress and English character, and consider from this point of view to what we owe it. There were originally some natural conditions favourable to the growth of our commercial and manufacturing energy. We had an extensive coast and numerous harbours. We had also abundance of iron-stone in convenient proximity to workable coal. Other nations either wanted these advantages or were ignorant that they possessed them. These favourable conditions developed in many individuals a special adaptability to commercial pursuits. The type was rapidly reproduced and continually improved until England stood, in the field of commerce, almost alone among the nations of the world. And what is there now to sustain our pre-eminence? Nothing, or next to nothing, except the type of national character, which has been thus produced. Steam, by land and sea, has largely diminished the superiority which we derived from the nature of our coast; and coal and iron are now found and worked in a multitude of countries other than our own. Our strength in commerce, like our weakness in art, now rests almost exclusively on the national character which our history has evolved.

Take another example of the character of a people produced partly by natural conditions of existence, but far more by the artificial conditions to which evil legislation has exposed it. What has made the typical Irishman what he now is? The Darwinian theory supplies the answer. Ireland is mainly an agricultural country, with supplies of mineral wealth altogether inferior to those of England, though by no means contemptible if they were but developed. This is her one natural disadvantage, and it is trifling compared with those which we in our perversity created. For a long period we ruled Ireland on the principles of persecution and bigotry, and left only two great forces at work to form the character of the people. All that there was of meanness and selfishness and falsehood was tempted to servility and apostacy, and flourished and perpetuated itself accordingly. All that there was of nobleness and heroic determination was drawn into a separate circle, where the only qualities that throve and grew were irreconcileable hatred of the oppressor and resolute but not contented endurance. The two types rapidly reproduced themselves, and as long as the external conditions remained unaltered, they absorbed year by year more and more of the people's life; as, if Darwinism is true, they could not but do. And what is the result now? A great part of a century has elapsed since we abandoned the wretched penal laws, and yet none can fail to see in Ireland the two prevailing types of character which our ancestors artificially produced, the only change being that the two types have become, to a certain extent, amalgamated in a cross which reflects the peculiarities of each. Whether future legislation may so far modify the conditions of Irish existence as to work a gradual change in the national character, is a question of much interest, but too large to be discussed just now. In any case we can scarcely expect the results of centuries upon a national type to be reversed in less than a succession of generations.

Still confining myself to the past, let me point again to the very marked qualities which the conditions of their existence have produced in the people of the United States. They started with a large element of English energy already ingrained into them; they have been reinforced by millions of emigrants presumably of more than the average energy of the various races which have contributed to swell the tide. Added to this, the Americans have enjoyed the natural stimulus of a practically unlimited field for colonisation. Only the resolute, self-reliant settler could hope to prosper in the early days of their national existence; and self-reliance approaching to audacity is the special type of character which on the Darwinian hypothesis we should expect to see developed, transmitted, and increased. How far this accords with actual experience, no one can be at a loss to say. There is probably not a nation in the world whose peculiarities might not be traced with equal ease to the operation of the same universal principle. And the moral of the investigation is this: Whenever a law is sufficiently ascertained to supply a full explanation of all past phenomena falling within its scope, it may be safely used to forecast the future; and if so, then to guide our present action with a view to the interest and well-being of our immediate and remote descendants. Read by the light of Darwinism, our past history ought to solve a multitude of perplexing questions as to the probable supremacy of this or that nation in times to come in the field of commerce, as to the effects of emigration and immigration on the ultimate type likely to be developed in the country that loses and in that which gains the new element of national life, and many another problem of no less interest to ourselves and to humanity.

The subject I have thus slightly indicated seems to me to deserve a closer investigation than it has yet received: and, strange as it will sound to the ears of politicians, I cannot doubt that, in this and other ways, statesmen, if they could open their eyes, might derive abundant aid from the investigations of science, which they almost uniformly neglect and despise. H.

THE PROGRESS OF NATURAL PHILOSOPHY

[We have been favoured by Professor Tait with the following extracts from his Introductory Lecture to his class at Edinburgh University, the object of the Lecture being "to show that Natural Philosophy is a *real* science, as tested by steady growth and progression, compared with other so-called Philosophies, which have periodic cycles, and come back after a generation or two into the old, old groove, with the same old rope of sand to be spun over again."—Ed.]

To enumerate in detail all the advances effected in natural philosophy during even the past year would take more time than is usually devoted to a lecture, so that I shall confine myself to a mere mention, not exposition, of a very few of the more interesting discoveries in cosmical science which have recently been made.

First. We have obtained an immense amount of new information as to the constitution of the sun. The total eclipse which was visible in India in the autumn of last year, was singularly well fitted for applying to the strange phenomena of the sun's atmosphere the comparatively novel powers of the spectroscope. Another total eclipse has recently been carefully observed in America, and the results obtained on these two occasions agree well with one another.

One of the most marked phenomena observed in a total solar eclipse is that which, first carefully described some thirty years ago, was called the "red flames;" very singular protuberances issuing apparently from the dark body of the moon, but which were conclusively proved in 1860 to belong to the sun. Had they been lunar phenomena, their dimensions would have been considerable; but it is easily shown that, belonging to the solar atmosphere, their dimensions are *enormous*, a hundred thousand miles being often no exaggerated estimate of their diameter. They must evidently be masses of extraordinary tenuity, else they could not rest in the solar atmosphere, which must be excessively rare at such an elevation. When the spectroscope was directed to them last year, it was at once perceived that they are fiery clouds, consisting mainly of hydrogen gas, heated so powerfully as to become self-luminous. This discovery once made, the total eclipse was seen to be unnecessary, and observations of these singular phenomena are now carried on every day. In fact, in anticipation that such would prove to be their nature, they had actually been sought for before the date of the eclipse. The reason why we can see them, in spite of the comparatively overwhelming light of the sun, is simply this, that the sun's light, which may be said roughly to consist of rays of all degrees of refrangibility, can by a sufficient number of prisms be spread over any desired extent, and thus weakened throughout; while the light from the red flames consists of but a few perfectly homogeneous rays, which may be indefinitely separated from one another, but cannot be individually weakened, by increasing the power of the spectroscope. The process, in fact, closely resembles that by which, with powerful telescopes, astronomers are enabled to observe stars in the day-time. The powerful telescope diminishes the apparent brightness of the sky; but the star has no sensible diameter, and remains undimmed. A singular fact observed is, that while the bright rays in these red flames, which are due to hydrogen, correspond exactly to well-known dark lines in the solar spectrum, due to absorption by the sun's atmosphere; there are others, especially a curious one in the yellow, which have no counterpart among the dark lines. Also the hydrogen lines are sometimes broader, sometimes narrower, than the normal spectrum of incandescent hydrogen requires; sometimes they are slightly displaced from their normal positions in the spectrum. The explanation (on purely physical grounds) of all these phenomena is now being carefully sought, and the connection of the red flames with sun-spots, as well as the singular peculiarities of the spectra of spots, are being recorded for future explanation. In this one direction alone a field has been opened up for inquiries which, even with our present appliances for observation, may well occupy the world for a generation to come.

Another striking phenomenon of a total solar eclipse is the (so-called) Corona of whitish light which appears to surround the dark body of the moon to a considerable angular distance. This also has been proved to belong to the sun. Part of its light is, no doubt, merely sunlight reflected from the matter of the sun's atmosphere, or from cosmical bodies revolving about the sun; for it has long been known to be partially polarised. But it is only within the last few months that *its* spectrum also has been observed, and found to consist mainly of bright lines—*i.e.* of a few rays of definite refrangibility. The positions of the most marked of these have been measured, and they are found to correspond with those of the light of terrestrial auroras! This is one of the most startling results yet obtained by observation; for the aurora is intimately connected with, or at all events has an important effect on, terrestrial magnetism, and it has been known for some time that disturbances in the sun have a marked effect on the magnetism of the earth.

Our sun is a variable star. It has been proved that its spots have an eleven-year period of maximum frequency. Laborious calculations are now in progress at Kew Observatory, with the view of tracing the cause of this periodic effect; and it seems already to be traced with some certainty to the planets, principally to Mercury, Venus, and Jupiter; the first, though very small, being very near, and the last, though very distant, being very large. Now, the red flames, or hydrogen clouds, are intimately associated with sun-spots. Hence we connect *their* frequency with the variability of sunlight. Now, it is only a year or two since an exceedingly well-marked case of a temporary star was visible in the northern hemisphere; a star, usually of inconsiderable magnitude, scarcely visible to the naked eye, suddenly blazed out with brightness rivalling that of Sirius. The spectroscope showed that it owed this increase of its light almost solely to incandescent hydrogen, the chief material of the flame-cloud that hovers over a *solar* spot.

Nor is it only in solar and stellar phenomena that these extraordinary recent advances have been made. Bodies even more puzzling and anomalous than the sun and stars are common enough in the universe. Many nebulæ, long imagined to be immense groups of stars, at such enormous distances that the several constituents were indistinguishable by the most powerful telescopes, have been shown to shine as glowing gas merely, rendering it probable that we have to deal with objects which, though certainly at vast distances from the earth, are probably not vastly farther away than some of the nearest stars. Possibly, in some cases, they may be much nearer, in which case they may be suns which have cooled, and are still surrounded by glowing gas, due to the impacts of small cosmical masses, or meteorites, on or near their surface. Or they may be vast systems of small cosmical masses in the act of grouping themselves by mutual gravitation, impact, and friction into a new star, the incandescent gas being due to the impacts and the friction. In them we may be actually watching the formation of a solar system.

Finally, let us consider what we have recently learned about comets—bodies which have hitherto puzzled the astronomer quite as much as have the nebulæ. Several ingenious speculations have recently been published on this very interesting subject, but I shall only mention one with any detail. There seem to be good grounds for imagining that a comet is a mere shower of stones (meteorites and fragments of iron). This at least is certain, that such a shower would behave, in its revolution about the sun, very much as comets are seen to do, and that, as we have reason to believe is the case with comets, it would be drawn out after a few revolutions, if it described a closed path, so as to be spread over the greater part of its orbit. If the earth, then, were at any time to intersect the orbit of the comet, it would pass through a stream of such stones, all moving approximately in parallel lines and with equal velocities. On entering the earth's atmosphere with the enormous relative velocity due to revolution about the sun in differently sized orbits, described sometimes with a retrograde motion, these fragments of stone would, by the laws of perspective, describe paths all apparently diverging from one point in the heavens, and these paths would be rendered visible by the incandescence of the meteorites due to friction of the air. Now this is exactly what we see, markedly in August and November every year, less definitely at other fixed periods. And the orbits of the August and November meteorites have been determined, and found to be identical with those of two known comets. I cannot enter very fully into this most interesting subject now, but I may say a few words more in explanation. Unfortunately, since spectroscopes have been in everybody's hand, no notable comets have appeared. [How strange it *now* seems to us that the magnificent comets of 1858 and 1860 were allowed to pass without having been looked at through a prism by anyone, whether as a matter of chance or of curiosity!] Such small comets as have been observed have given *continuous* spectra from their tails, so far as could be judged with regard to an object so feebly illuminated. This, then, it would appear, is simply reflected solar light. The heads, however, give spectra somewhat resembling those of the nebulæ I have just mentioned—the spectra of incandescent gases. This is quite consistent with the descriptions given by Hevelius and others of some of the grander comets; which presented no peculiarities of colour in the tail, but where the head was blueish or greenish. Now these appearances are easily reconciled with the shower-of-stones hypothesis. For the nucleus, or head, of a comet is that portion of the shower where the stones are most numerous, where their relative velocities are greatest, and where, therefore, mutual impacts, giving off incandescent gases, are the most frequent and the most violent. This simple hypothesis explains easily many very striking facts about comets, such as their sometimes appearing to send off *in a few hours* a tail many hundreds of millions of miles in length. Wild notions of repulsive forces vastly more powerful than the sun's gravity have been entertained; bold speculations as to decomposition (by solar light) of gaseous matter left behind it in space by the comet have also been propounded; but it would seem that the shower-of-stones hypothesis accounts very simply for such an appearance. For, just as a distant flock of seabirds comes suddenly into view as a dark line when the eye is brought by their evolutions into the plane in which they fly, so the scattered masses which have lost velocity by impact, while they formed part of the head, or those which have been quickened by the same action, as well as those which lag behind the others in virtue of the somewhat larger orbits which they describe, show themselves by reflected solar light as a long bright streak whenever the earth moves into any tangent plane to the surface in which they are for the time mainly gathered.

It is a most valuable principle in physical science, never to be lost sight of, that we must not seek to explain by the assumption of new species of force or action any phenomena which have not been recognised to be inexplicable by means of properties of matter or motion already proved to exist. Before leaving this subject I must refer to the extraordinary fact, lately ascertained, that the spectrum of the head of one of the smaller comets is that of incandescent vapour of *carbon*, of a substance which, with the most tremendous heat attainable in our laboratories, we cannot even melt, much less reduce to vapour: so that to find its spectrum we are obliged to employ it as it exists in olefiant gas or other combined form. But it is premature to speculate further on such incomplete data as we yet possess with respect to the spectroscopic appearances of comets. It is not rash to venture the prediction that the very first application of the spectroscope to a really fine comet will give us at least as much additional insight into the nature of these bodies as the total eclipse of 1868 gave with regard to the atmosphere of the sun. P. G. TAIT

DANA'S MINERALOGY

A System of Mineralogy: Descriptive Mineralogy comprising the most Recent Discoveries. By James Dwight Dana, Silliman Professor of Geology and Mineralogy in Yale College, etc., aided by George Jarvis Brush, Professor of Mineralogy and Metallurgy in the Sheffield Scientific School of Yale College. Fifth edition, 8vo. pp. 827, figures 617. (London: (Trübner & Co.)

II.

EXCEPT in the subdivisions of the silicates, Professor Dana has adhered pretty nearly to the classification adopted in his fourth edition; which accords also in its general features, though not in its details, with that on which the minerals in the British Museum are arranged. The arrangement of the silicates in his new edition is a step that must be called tentative towards a simpler and more philosophical classification of these numerous and important salts. We certainly feel some hesitation in adopting either the terminology or the divisions Professor Dana introduces. The terms bi- and uni-silicate are not happy for the expression of oxygen ratios; not so happy, for instance, as the term singulo-silicate used for the latter by Rammelsberg, or the ortho-silicates of Odling. We own to a partiality for the view of Dr. Odling regarding the different classes of silicates, on the ground partly of the harmonious relations he introduces between these and other multibasic salts, and also from the satisfactory way in which these very important minerals group themselves as ortho-, para-, or meta-silicates. We may take another occasion for illustrating this, and pass on to Professor Dana's new and scholarlike handling of the whole question of nomenclature.

Our author has shirked no labour or odium in the way he has faced this question. That trivial names are absolutely necessary in mineralogy no one who has dealt with the subject at all philosophically will question. Even such semi-trivial terms as ferrous aluminic garnet, calcioferric or magnesio-aluminic garnet, are almost too long for use; but how should the composition of these bodies be described by names purely chemical?

Generally, therefore, we feel bound to acquiesce in the use of a trivial name for each mineral, and to subscribe to the rules Professor Dana has laid down for such names. These may be stated as the use of the termination *-ite*, except in names that have a hold on literature or use; some care in adhering to proper etymological principles in derivative names; and, finally, the law of priority of claim accorded in general, but with proper exceptions, to the first describer of a mineral. In applying these rules, Dana retains, so far as wec an enumerate them, some thirty-four names not ending in *-ite*, and changes about forty-seven of the names more or less generally received.

We cannot, however, concur in the Professor's criticism in his derivation of the spellings in all cases from the pseudo-Latin names given to metals by the chemist. Thus, to call nickeline "niccolite" and not "nickelite" is to lose sight of an essential part of the original form of a word of which, in fact, our familiar term "Old Nick" is the English shape. Surely, too, bismuth ochre should become not bismite, but bismuthite. Nor can we agree with the dismissal by Dana of the term hemimorphite, which was given to the monohydrated dizincous silicate by Kenngott. Our author reverts to the old name of calamine, between the use of which and of smithsonite, as names sometimes attached to the zinc carbonate, sometimes to the silicate, there has long existed a confusion that is best ended by the adoption of at least one new name. And Kenngott's term had at any rate this great merit, that it seized a characteristic of the crystallised silicate, by virtue of which it stands conspicuous among almost all other minerals, and certainly is distinguished from the other calamine, the character, namely, of being truly hemimorphous; that is to say, of presenting a given crystalline form all the planes that should occur on one side of a plane of symmetry, and none of the planes of that form that would, if the crystal were holosymmetrical, be met with on the other side of that plane of symmetry. We plead, therefore, strongly in behalf of Kenngott's name. As regards the merging of the term hornblende in that of amphibole as carried out by Dana, we would prefer to see the whole nomenclature of these augitic and hornblendic minerals so handled that we might have a general term for all the groups of minerals united under a common chemical type; and separate terms, still generic, that might embrace the minerals, whether of prismatic, oblique, or anorthic type, that present the kind of homœomorphism that demarks these groups. The trivial names for the different species or varieties under each group would remain nearly as they are. Now Professor Dana selects the term amphibole for the most general of these expressions, and he includes under a pyroxene sub-group enstatite (prismatic), wollastonite (oblique), and what he further calls pyroxene (oblique but homœomorphous with enstatite); and then after a spodumene sub-group he introduces an amphibole subgroup. We venture to think that the term "amphibolic minerals" used for the whole might well be made to embrace: Firstly, an augitic group, including as its members, (*a*) enstatite, with hypersthenic minerals, (*b*) diopside, with sahlite, hedenbergite, and the fassaite (aluminous varieties, (*c*) spodumene and petalite, (*d*) achmite, (*e*) rhodonite and babingtonite; Secondly, a hornblendic group, embracing as its subdivisions, (*a*) kupfferite with anthophyllite, (*b*) tremolite, with actinolite, grünerite and the pargasite (aluminous) varieties, (*c*) arfvedsonite; Thirdly, wollastonite.

Of course only a few leading varieties are here noticed. As regards other names introduced by Professor Dana, we are fain to accept even so uncomfortable a name as prochlorite in place of chlorite, a term to the chemist's ears so ambiguous in its sound. To most of Professor Dana's other changes, also, we with more or less of readiness subscribe; though against the barbarous conversion, not newly introduced into this edition of Dana, of one of the most ancient terms in mineralogy, pyrites, into pyrite, in flagrant defiance of all etymological principle, we must continually protest.

We have noticed the more important novel features in this fifth edition. There is still much to be said regarding the degree of fulness with which different parts of the descriptions of the minerals are given, such as the pyrognostic characters, and the treatment of the chemical analyses. But when we consider the vast amount of matter collected into some 800 closely-printed pages, the scrupulous care with which so enormous a number of references has been made to the labours of mineralogists, extending over the whole area of the scientific literary works of a century past—ay, and often into the two or three centuries before that; when we remember that the progress of the science up to 1868 is thus fully, conscientiously, and elaborately recorded, we can only thank Professor Dana, in the name of European mineralogists, for the very valuable volume by which he has so much lightened their labours: and with his name we must associate that of the accomplished mineralogist who has shared his labours, Prof. Brush. If in fulness their joint work does not come up to the now, alas! almost obsolete work of Hausmann, it is three times more portable. W. H. Miller's invaluable book, modestly called by him an edition of Phillips, is again a mineralogical crystallography. The only book that at present professes to cover the ground occupied by Professor Dana's work is the admirable *Manuel* of Des Cloizeaux, of which, however, only one volume has yet appeared, but which unites to the sort of originality in crystallographic and physical research which gives Miller's work its value, something of the universality of treatment which Dana gives to his mineral species. We wish, indeed, that M. Des Cloizeaux could have given up the microscopic fractions that characterise the French system of crystallographic notation, and torment the crystallographer's hardly-used eyes, for the more elegant notation of Miller, as he has in fact adopted the stereographic projection. But we look keenly forward to the publication of the second volume at the hands of the new member of the Institute; and, while we do so, we feel confident that as in matter it will be as masterly as the first, and as indispensable to the scientific mineralogist, so it will satisfy scientific needs that differ in kind from those felt by a large proportion of the practical men in whose hands Professor Dana's book will still be a standard treatise.

We have said enough to point out the extreme value of Professor Dana's book, which, taken as an indication of the present state of science in America, is of the best possible augury; and we may add that mineralogy is not the only science represented in high-class American text-books. Chauvenet's "Astronomy" is another instance which at once suggests itself.

N. STORY MASKELYNE

BIBLIOTHÈQUE DES MERVEILLES

L'Acoustique, ou les Phénomènes du Son. Par R. Radau. Ouvrage illustré de 114 vignettes.—*L'Optique.* Par F. Marion. Ouvrage illustré de 70 vignettes sur bois, et d'une planche tirée en couleur.—*L'Electricité.* Par J. Baille. 71 vignettes.—*Les Forces Physiques.* Par Achille Cazin. 58 vignettes. (Hachette; Paris and London.)

Thunder and Lightning. By W. de Fonvielle. Translated from the French and edited by T. L. Phipson, Ph.D., F.C.S.—*The Phenomena and Laws of Heat.* By Achille Cazin. Translated and edited by Elihu Rich. (London: Sampson Low, Son, & Marston.)

THESE works form part of a series having the general title, "Bibliothèque des Merveilles," which will be extended to about a hundred volumes, and will form a Cyclopædia of the more prominent wonders of the universe —of all that is "most admirable in Nature, in the sciences, in industry, in history, in man." It is published under the direction of M. Edouard Charton, and the main object to be attained by it is "seconder l'heureux mouvement qui porte aujourd'hui toutes les classes de la société vers l'instruction." The majority of the volumes which have already appeared relate to applied science, and here we may remark that MM. Hachette have done much to disseminate a taste for science among all classes by the publication of works suited to the most varied capabilities and the most varied means. Commencing at one end of his series, we have twenty and thirty franc "editions de luxe" of the *Le Ciel* and *Phénomènes de la Physique* class; and, passing through various gradations, we arrive at length at the two-franc volumes of the "Bibliothèque des Merveilles." The last volumes have much to recommend them; they are, for the most part, popular in style; they are well illustrated, well printed, and undeniably cheap, and they are written by men, among whom are many who are engaged in giving instruction in one or other of the multifarious educational establishments of France. We have no series of books in this country to compare for excellence and cheapness with these, and this mainly arises from the fact that science does not form an essential part of our educational system, as it does of that of France. The volumes of the "Bibliothèque des Merveilles" can be sold in France at less than one-half the price which would be demanded in this country, because the publisher can feel certain when he issues his work that a large number will find their way into the various schools and colleges of the Empire.

M. Radau's "Acoustics" is quite a type of a French popular scientific work; with every desire to convey as much information as possible, the author will not give up a certain amount of light amusing matter, and a popular style. How surprised we should be in this country to see a woodcut of a dancing bacchante (somewhat like Salvioni) in a chapter entitled "Le Timbre," and not far from a representation of the "Progression d'une vibration longitudinale." A vague unscientific reader might be led to find an analogy between Cagniard de la Tour's syren and Radau's bacchante; the bacchante occupies a full page, while the syren has a little strip of space in the text, and we ultimately discover that the former has been introduced solely for the purpose of showing the *crotalon.* Among the many good features of this book, we may mention that it enters somewhat fully into the growth of music, and traces the connection between the science of sound and the art of music. From this we learn that the names of the first six notes were introduced by Guido of Arezzo, in 1026, and that they were the commencement of words taken from a hymn which is still sung on S. John's Day :—

> "*Ut* queant laxis *re*sonare fibris
> *Mi*ra gestorum *fa*muli tuorum,
> *Sol*ve polluti *la*bii reatum,
> Sancte Ioannes."

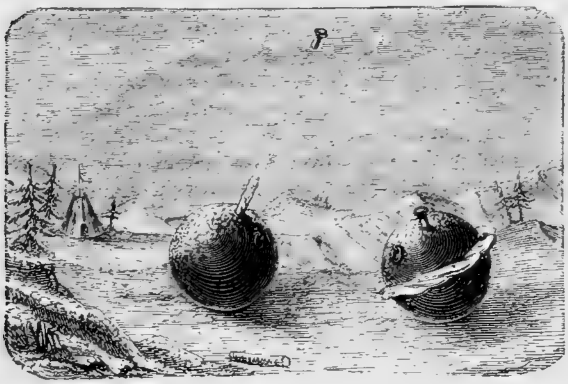
The seventh note was designated *si*, in 1684, by Lemaire, and was taken from the initials of Sancte Ioannes. We may mention the chapters on the reflection of sound, on interference, and on the voice, as being of special interest. In the first of these the famous echo of Athanasius Kircher is described ; the echoes in this case are produced by walls placed at certain distances apart, and at right angles to another wall ; the observer cries :—

> " Tibi vero gratias agam, quo clamore?"

and the echo answers :—

> " Clamore—Amore—More—Ore—Re.

The work on "Electricity," by M. Baille, is of a less popular character than the above ; it treats solely of the applications of electricity, and is divided into four parts: Electric Telegraphy, Induction Machines, the Electric Light, and Galvanoplastic Art. M. Cazin has previously published a work on Heat in this series, and his "Forces Physiques" is of the same character ; they are essentially sound, accurate in detail, and are well adapted for those who are commencing the study of physics. Many of these works have been translated into English, and we are glad to know that the greater number of the books of the "Bibliothèque des Merveilles" which have not yet appeared are now in course of translation, among them



EXPANSIVE FORCE OF FREEZING WATER

L'Acoustique, which ought to be used in all schools in which music is taught, and therefore notably in Ladies' Schools. M. Marion's *L'Optique* has been translated by Mr. C. W. Quin, who has introduced a chapter on the spectroscope, unfortunately without an illustration. The work is concluded by a full account of the ghost illusion of which we heard so much a few years ago. M. de Fonvielle's "Thunder and Lightning" retrogrades somewhat from the works noticed above, in that it is of a more sensational character. Thus we have full-page woodcuts of "a murderer struck by lightning;" of a broad stream of lightning meeting a lady as she comes upstairs; of an explosion of gas by lightning, and so on. The best woodcuts in the book are those which represent the photographic reproduction of an electric spark. M. Cazin's work on

[illegible]

"Heat" is strictly scientific in character, and might with advantage be used as an elementary text-book in schools.

We hope before long to find this series of books altogether naturalised in this country, and no time could be more fitting, since science has at length been recognised as a useful educational engine.

G. FARRER RODWELL

OUR BOOK SHELF

Chemical Exercises. — *Arithmetical Exercises for Chemical Students.* By C. J. Woodward, B. Sc. (London : Simpkin, Marshall, and Co., 1869).

MR. WOODWARD, who is lecturer on chemistry and physics at the Midland Institute, Birmingham, has printed, under the above title, a set of ten very useful cards, to assist students in familiarising themselves with the more common numerical calculations of chemistry. Each card contains, first the *data*, and secondly the *method* of a particular kind of calculation ; this is followed by a number of questions. Ten subjects are gone over in this way. I may describe them as : (1) the metric system; (2) conversion of thermometric readings, and reduction of gaseous volumes : (3) specific gravity; (4) formulæ as yielding percentage composition ; (5) percentage composition a source of formulæ ; (6) weight and chemical effect ; (7) volume and chemical effect ; (8) reactions of gases ; (9) the crith and thermal units ; (10) specific, atomic, and latent heat. This range is amply sufficient for all ordinary purposes.

Although there are great conveniences in the use of a card system of instruction, especially when clearness in the printing is as well attended to as in these specimens, an objection lies against it that, in this case particularly, a good deal of repetition is unavoidable. In Mr. Woodward's *data*, the same symbolic values are tabulated over and over again. Could not these have been collected in a single group, once for all? Much space might also have been gained for questions by giving what corresponds to a title-page only on the first card. Thoroughly systematic names, based on a *single* principle now in use, ought alone to be employed in elementary teaching. "Argentic chloride," "silver chloride," "corrosive sublimate," are names of three quite distinct kinds which, we have found, the author employs without comment. A nomenclature card would indeed be a valuable prefix to the series. It would also be an advantage to append answers to all the questions.

Clearly expressed rules, and good examples of the mode of applying them, are so obviously useful to students, that it only remains to add that Mr. Woodward has done his work well. E. J. M.

Agricultural Engineering.—*Der Cultur-Ingenieur.* Herausgegeben von Dr. F. W. Dünkelberg. (Brunswick, 1869.)

THIS periodical, a quarterly journal in its second year of publication, professes to deal with all questions of applied science affecting agriculture. The papers contained in the present number are mostly of a thoroughly practical character. They treat of such matters as the testing of steam-engines at agricultural exhibitions, the examination and adjustment of levelling instruments, the cause of boiler explosions, the mean velocity of water in canals and rivers, and the usefulness and profitableness of various machines for agricultural purposes. One paper gives a description of English locomotives for use on ordinary roads. The journal is well got up and amply illustrated.

The Microscope and its Use. By Dr. H. Hager. (*Das Mikroskop und seine Anwendung.* (Berlin: Springer.)

THIS little work gives, in less than a hundred pages, first, a brief account of the microscope and of microscopic appliances; secondly, a still more rapid description of common microscopic objects. It is, in fact, very much like our own "Carpenter on the Microscope," on a very reduced scale. The first part is written with great sense, and very much to the purpose. We are not surprised that the little work has received in Germany the unusual honour of a third edition.

Freshwater Radiolaria.—*On some Freshwater Rhizopoda, new or little known.* By William Archer. (*Quarterly Journal of Microscopical Science*, July and October, 1869.)

MR. ARCHER, of Dublin, who is well known as one of the contributors to Pritchard's "Infusoria," and a careful observer, has for the last two or three years chronicled in the Proceedings of the Dublin Microscopical Club, published in the *Quarterly Journal of Microscopical Science*, the occurrence of Radiolarian-like Rhizopods in the moor-pools of Ireland. At the end of last year Dr. Focke, of Bremen, described and figured a few of the same forms, bearing a likeness to some which have been considered as belonging to the genus Actinophrys, or sun-animalcules, of Ehrenberg. Mr. Archer has at length published the description of his new species, with full illustrations in three folding coloured plates. Many of these new freshwater Radiolarians, like the marine forms which they appear to represent in fresh water, carry siliceous spicules; they are mostly globular, and have a capsule surrounded by protoplasmic matter, which is drawn out into very long and delicate threads or rays, whilst the spicules are aggregated so as to form a loose sort of skeleton. In one large species Mr. Archer found several globular capsules united in one individual (*Raphidiophrys*). The contents of the capsules are coloured green in some instances, in other species they are red, or colourless. These most interesting animals are found only in moor-pools, and are, therefore, not to be got at by every observer. It is, therefore, very curious that besides Mr. Archer's and Dr. Focke's publications in this year, Dr. Richard Greef, of Bonn, should also have turned his attention to them, without being aware of Mr. Archer's work. In No. 3 of Max Schultze's *Archiv* for this year, Dr. Greef has a paper and plates, describing some species and genera *identical* with those of Mr. Archer, who, however, has precedence by some months. The fresh-water Radiolaria, it has been suggested, stand in the same relation to the more exuberant and highly developed marine Radiolaria, as do the fresh-water Hydrozoa represented by Hydra to the much more numerous, more brilliant, and varied marine Hydrozoa. E. R. L.

The Annals and Magazine of Natural History.—No. 24. December, 1869. (Taylor and Francis.)

THE last number of this journal contains several valuable papers, of which the most important is undoubtedly Mr. Carter's description of the Development of *Sorastrum spinulosum*, which will be read with interest by botanists. Dr. Leconte, of Philadelphia, contributes a list of beetles collected in Vancouver's Island by Messrs. H. and J. Matthews, with descriptions of a considerable number of new species. Dr. Leconte does not cite any of the species from the same locality described by Mr. Francis Walker in Lord's "Naturalist in Vancouver's Island and British Columbia;" in all probability he will find that some of his supposed new species are already described.—Mr. T. Vernon Wollaston publishes a continuation of his paper on the Coleoptera of St. Helena, the general results of which we propose to give on its completion.—A third entomological paper is by Mr. Fred. Smith, on the Parasitism of *Rhipiphorus paradoxus*, in answer to a communication in the November number by Mr. Andrew Murray, in which that gentleman maintained that the larva of *Rhipiphorus*, which is always found in the cells of wasps, is a parasite rather in the classical than in the natural history sense of the term; that is to say, that it merely lives upon the food furnished to the wasp-larva, and does not feed upon the substance of the latter. In opposition to this view, Mr. Smith cites observations made by himself and by the late Mr. F. Stone, which show clearly enough that the larva of *Rhipiphorus* is not hatched until the wasp-larva is approaching maturity, that it speedily fastens upon its companions, and appropriates the latter's materials with so much avidity as to attain its full growth in about forty-eight hours.—Other purely zoological papers are—A description of a new British spider belonging to the genus *Epeira*, by Mr. John Blackwall; descriptions of two new species of sun birds from the Island of Hainan, by Mr. Robert Swinhoe; and a notice of some nondescript bones in the skull of osseous fishes, by Mr. George Gulliver. The bones referred to in the last-mentioned paper are to be found in the head of the codfish at the hind part of each post-frontal bone. There is one on each side of the head, and their form is that of a sub-conical cup. The author calls them *expost-frontal ossicles.* Similar limpet-shaped ossicles hitherto unnoticed occur in other parts of the head.—In a joint paper on the Nomenclature of the Foraminifera (the thirteenth of a long-continued series), Messrs. Jones, Parker, and Kirkby describe the extraordinarily varied forms under which a species, to which they attribute the name of *Trochammina pusilla*, presents itself. These forms, which have of course received a great number of different names, are represented by the authors on a plate; they occur fossil in almost all formations from the Permian to the Tertiaries, and some of them are living in our present seas.—In a short contribution to Jurassic Palæontology, Mr. Ralph Tate indicates the necessity for breaking up the great genus *Cerithium*, and notices that the genus *Kilvertia*, established in 1863 by Lycett, at the expense of *Cerithium*, is identical with *Exelissa*, Piette (1861), of which he describes a new British Liassic species. He also proposes the formation of a new genus, *Cryptaulax*, for another group of *Cerithia*, in which the aperture more resembles that of *Chemnitzia*, and the posterior canal is concealed by the outer lip.

THE JAPANESE

JAPAN is a country of which the outer barbarian world as yet knows little. By slow degrees, however, the great wave of progress is making inroads even in that jealously guarded group of islands; but as yet it is but in three places, not in themselves of much importance, that the country is open to foreign commerce. The capital is only accessible to diplomatic agents, and the excursions which have been made into the interior have been of an imperfect kind.

Yeddo, with the great volcanic cone of Fusiyama prominent in all the views of the city; Yokohama, Kanagawa, Kagosima, the Central Sea,—these names bring before us almost all that we really know about Japan. There are maps of the empire to be found, which show the divisions and towns of the great island of Nippon, and also of the smaller islands of the group; but we know little of them, except their names and their relative position. The day is yet to come when the physical geography of this fine group of islands will be laid bare to the researches of Western men of science. The latitude of the islands, together with the influence of that warm ocean current which may be called the Pacific Gulf Stream, ensures for them a mild climate; and rice, cotton, and silk are among the varied productions of this favoured country. At the same time, it must not be forgotten that earthquakes are not unusual, that the volcanic fires are not yet extinct in Japan, and that the shores are sometimes visited by the fierce typhoons which desolate the neighbouring seas.

The people themselves, however, their religion and government, their houses, their manners and customs, have been subject to observation in the different towns open to foreigners; and several accounts have been laid before the public. Of these, none is more interesting than the narrative of his life in Japan which has been given to the world by M. Aimé Humbert,* the Swiss minister in Japan, who arrived there in the year 1863, and who has prepared a narrative of his sojourn in Yokohama and Yeddo, and his excursions in the neighbourhood of these places, which is extremely lively and interesting. M. Humbert's observations are chiefly upon the people; and his remarks, and the number of illustrations with which the descriptions in his two magnificent volumes are enriched, bring before us the Japanese, at least of the cities, with very great vividness. They live and move before our eyes: we see them in their temples, in their court dresses, in their everyday life, in their amusements, in the pursuit of their trades and professions, in the exercise of justice, in the celebration of their annual fêtes.

The Japanese, M. Humbert thinks, are of diverse origin. Some possibly came from China, some were Mongols from the neighbouring Corea; but doubtless many derive their descent from ancestors whose frail boats were drifted from the Malaysian Archipelago far to the south. The Japanese are not a tall race; the head and chest are generally large, the legs short, the hands small and often beautiful, the hair long, smooth, and black, the nose well-defined, the eyes more prominent than those of Europeans, the dominant colour of the skin an olive brown, though the colour varies from an almost copper brown to a dull white. The women are lighter in colour than the men, and in the higher classes they are often perfectly white.

In their domestic relations the Japanese are kindly, especially to their children, for whom they have intense affection, and for whose pleasure they will make any sacrifice. The Japanese takes but one wife; but he has it in his power to take secondary spouses, and not unfrequently avails himself of the privilege. The Japanese women are in a state of extreme subjection to their lords.

The religion of the vast mass of the people is Buddhism, with a vast array of bonzes or priests, and great temples, colossal idols, and a complicated system of worship. One of the grandest of the idols is well described by M. Humbert; it is the image of Diaboudhs, the great Buddha:—"The road to the temple is distant from all habitations; it winds between tall hedges, then a straight road mounts up between foliage and flowers, then a sudden turn follows, and all at once, at the end of an avenue, is seen a gigantic divinity of copper, seated in a squatting attitude, with the hands joined and in the attitude of contemplative ecstasy." The acceptance of the Buddhist doctrine of the ultimate passing of man into annihilation produces, it is said, in the Japanese, that wonderful disregard of human life which is one of their most remarkable characteristics. But besides the Buddhist theology, there is also a worship of the Kamis, or ancestral divinities, which prevails in Japan. The Kamis are not always the ancestors of separate families; the greatest of them, indeed, are the fabled ancestors of the whole Japanese race. But the belief in these ancestral deities leads to a vast amount of reverence being paid to the memory of the dead, and to annual visits to the tombs of the departed. These visits to the hills of the dead which surround the towns

HOTEÏ

are distinguished by much illumination of torches, and terminate with a setting afloat of little boats, each with lights, which drift down the river at night, and of which the lights are one by one extinguished. There is, besides, a belief in a number of tutelary deities, some of whom are half-mystic heroes—gods who preside over the events of life, whose *fêtes* are occasions of much national rejoicing, and whose influence contributes to counteract the sombre effects which an exclusively Buddhist belief would produce. Of one of these, Hoteï, the accompanying illustration gives a representation, the fac-simile of a Japanese drawing. Hoteï is the personification of contentment in the midst of poverty. He is the sage who possesses no worldly goods—the Diogenes of the great Nippon. His sole belongings are a scrap of coarse hempen cloth, a wallet, and a fan. When his wallet is empty he only laughs at it, and lends it to the children in the street, who use it for their games. For his part, he converts it by turns into a mattrass, a pillow, a mosquito-net: he seats himself on it as on an inflated skin to cross a current of water. Hoteï leads a somewhat vagabond life. He is sometimes met mounted on the buffalo belonging to a cultivator

* Le Japon illustré, par Aimé Humbert, ancien plénipotentiaire de la Confédération suisse. 2 vols. 4to. L. Hachette et Cie, Paris.

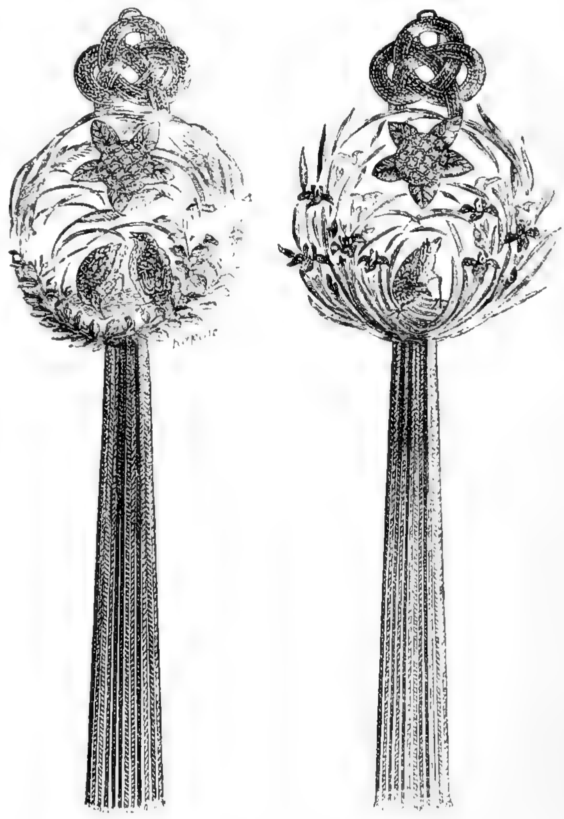
of the rice-fields. All the country-folk are his friends. He sleeps under the trees; and the children awake him. Then he takes them in his arms, tells them stories of the sky, the moon, the stars, all the magnificence of nature, treasures which no one knows better than himself how to enjoy.

The government of Japan is a species of feudal confederation, with a theocratic head. The Mikado, the son of the gods, and hereditary emperor, is the representative of the sacred power; but the civil and military administration rested until very recently in the hands of his lieutenant-general, the Tycoon, whose headquarters were in Yeddo. The great princes, or Daimios, are in many instances almost independent, and they are only held in subjection by being obliged to have a double residence; one on their own estates, and the other in Yeddo, where their families are kept as hostages for their good behaviour. The Yaconins, or military following of the Daimios, constitute a turbulent class of the population, bound solely to their feudal lords, and ready for any fray that may happen. It is among the Japanese of the upper classes that the act of *hara-kiri* is practised. This is a suicide, nominally accomplished by plunging a knife into the bowels, but really, in cases of punishment, by the assistance of the person who stands prepared to strike off the head of the victim at the moment when the knife is placed for the fatal blow.

The Japanese are a cultivated people, with letters and literature partly of Chinese origin, but modified in order to adapt them to Japanese use. They have also a distinct national history; and their literature, though not rich in philosophical disquisitions, abounds in legends, in fables, in satirical descriptions. The Japanese have also highly developed artistic tastes; and painting, drawing, and sculpture are followed as distinct professions. The Japanese drawing does not always satisfy European exigencies with regard to perspective; but the colouring is brilliant, and in Japanese sketches, whether of plants or animals, people or landscape, there is a breadth, life, and truth, which many European artists of much higher pretensions might envy. In fact, the best notions that we can obtain of Japanese life and its surroundings are to be derived from the numerous sketches by Japanese artists which exist, and which represent the people pursuing their daily occupations. M. Humbert has profusely illustrated his work with pictures—partly facsimiles of native work, partly drawn after sketches made by Japanese artists. The Japanese have what the Chinese seem to be deficient in, a strong sense of humour; and this they exhibit in a very striking manner in their sketches, in which human beings are represented by typical animals. Thus, sketches may be seen in which an old bonze is represented as a wolf, a group of Buddhist nuns as weasels, and a company of rats acting as rice-merchants.

The artistic tastes of the people and their love of Nature are both illustrated by their passion for flowers, and by the skill with which they are cultivated. No feast is considered perfect without flowers, and flower-shows meet with as much approbation in Japan as in England. The Japanese gardeners exhibit great skill in the arts of raising new varieties of flowers, of grafting plants, so that different flowers and leaves grow in what appear to be branches of the same plant; and they are, above all, learned in the manufacture of dwarfed plants, which are in great request as house ornaments. The Japanese delight in gardens, and they lay out small pieces of ground with wonderful skill, contriving to "give ample space to narrow bounds" with much ingenuity. The vast *enceinte* of Yeddo encloses much garden ground, and the people make at least three definite excursions to the suburbs at different times of the year, to see with their own eyes how the seasons progress. These excursions are often made as picnics, in which merry family groups take part. The Japanese have also a great fondness for aquaria; every house possesses one, and an aquarium, with small fish in it, is a very common object to be seen in houses.

The Japanese common people, both the *bourgeoisie* and the lower orders, take life with as much enjoyment as possible. The *fêtes* of various gods, who are patrons of one or other of the numerous industries exercised, afford occasion for long processions, with great displays of banners and symbols, for much merriment, and a not always dignified or moderate consumption of saki. Nor are the pilgrimages made to the sacred snow-covered Fusi-yama and to the various habitations of holy hermits altogether without alleviations. The events of domestic life—births, marriages, deaths, presentations of children in the temple, the coming-of-age of boys, when they have completed their fifteenth year, visits to the burial-places of ancestors—all afford occasion for friendly meetings, and for much ceremonial.



SILKEN ORNAMENTS

Theatrical entertainments, and the performances of wrestlers, acrobats, jugglers, and ballet dancers are among the public amusements to which the Japanese are passionately attached. The theatres at Yeddo to which foreigners have had access are chiefly those patronised by the *bourgeoisie;* but among the audience are to be found nobles who assume a dress intended to show that they pay their visit incognito. Wrestlers are under special imperial patronage, and are much favoured by the people. The contests consist chiefly of struggles as to which of two competitors shall by mere weight push the other out of a circle marked off by bags filled with straw. Japanese wrestling is utterly unlike what is understood in England by the same term; and the men engaged in it are generally in a fleshy condition which, among ourselves, would be considered utterly incompatible with a state of "training." The feats of performers who execute wonderful tricks of balancing, and of jugglers who do the "butterfly trick," which has lately been so popular among ourselves, elicit great applause. So popular also are ballet performances, that even the priests, in some of the great temples, engage in sacred dances to add to the "legitimate" attractions of the places of worship. Fencing is a favourite amusement, and is taught to women.

The public baths where men and women conduct their ablutions in the sight of all the world, and the tea-houses, at which women wait on the guests, are two features of Japanese life which are very strange to European eyes.

The town of Yeddo has a very striking physiognomy, so to speak. To the south are the suburbs on the shores of the bay; in the centre the citadel and the dwellings of the nobility; to the south-east, the trading town; to the east, the quays and bridges of the great river, and on the left bank the industrial city of Hondjo; to the north lie the temples, the fields where fairs are held, the theatres and public places of amusement. The western quarters are occupied by the general city population; and the suburbs of the north and west are full of verdure and flowers.

Yeddo has been calculated to have 1,800,000 inhabitants, although as an important city it only dates from the beginning of the 17th century. It is the northern termination of the great military road, the Tokaido, which traverses the empire from Nagasaki to Yeddo, near to which are built towns, villages, and many houses of the nobility, and along which the Daimois pass when proceeding to their compulsory residence in Yeddo. The modes of travel in use are either horseback, or palanquins carried by men. These latter are of two kinds; the norimon, closed on all sides, and in use among the upper classes, and the cango, light in construction, open at the sides, and used by the common people. As the Daimois pass along with their two-sworded retinue, all passengers give way to them, those that are on horseback dismount, and all stand bending low till the great man has gone on his way. The refusal of foreigners to submit to this fashion has led to the murder of more than one.

Yeddo is a busy town. Cotton and silk manufactures of a delicate kind, the making of porcelain, dyeing, tanning, the working in metals, the carving of stone, wood, and ivory, the manufactures of paper and of leather are all carried on in the town. (An illustration of the delicate silk embroidery which is made by the Japanese is given in the accompanying woodcuts, which represent silken dress ornaments.) In the suburbs, especially of the northern part, the gardens of the florists, the rural tea-houses, and the rice-fields are found. Minor industries —those of the makers of chop-sticks, of toothpowder, of dolls, of makers of mats, basket-work, and boxes, down to that of the humble rag picker—are to be found exercised in the small shops, or in the streets of Yeddo. The streets are full of life. The trades are carried on by the artisans, the jugglers and acrobats exercise their skill, men, women, and children pass along, bent on amusement or pleasure; here an enormous artificial fish, or a flag displayed at a house, announces the birth of a child; there a wedding procession takes its way; a Daimio passes, and all bow to the ground; an alarm of fire from one of the many watchtowers of the city calls out the firemen; the watch goes on its rounds; beggars exercise their arts as a kind of sacred trade—in a word, all the complicated machinery of a busy town life is to be seen in active operation, in what was the great capital of the Tycoon.

A jealous exclusion of foreigners prevailed in Japan for more than two centuries and a half; the only favoured people being the Dutch, who were permitted to build a small factory at Decima, and to send thither annually two trading vessels. The arrival of foreigners and their trade were regarded by the Tycoon and the nobles with dislike, chiefly because of the possibility that the introduction of new ideas might upset the old order of things; and the residence of foreign Ministers in Yeddo was rendered so uncomfortable, and even dangerous, that the legations settled in Yokohama as their permanent place of residence.

Recent events have effected a great change in the government of Japan. The Mikado, the theocratic emperor, has abolished the office of Tycoon. He has left his sacred city, and established himself, temporarily at least, in Yeddo, where the legations are in greater security than before. The export of tea and silk, already great, is increasing: and it is possible that Japan, so long isolated, may in time resume her relations with the outer world, and become, as her early records show her to have been, a busily trading, progressive nation.

It will be seen from the foregoing notice that M. Humbert's volumes contain an immense mass of valuable information as well as exquisite illustrations and lighter matter.

J. A. CHESSAR

FOOD OF OCEANIC ANIMALS

THE receipt of an interesting paper by Professor Dickie, entitled "Notes on range in depth of marine Algæ," lately published by the Botanical Society of Edinburgh, induces me to call the attention of physiologists to the fact, that plant-life appears to be absent in the ocean, with the exception of a comparatively narrow fringe (known as the littoral and laminarian zones), which girds the coasts, and of the "Sargasso" tract in the Gulf of Mexico.

During the recent exploration in H.M.S. *Porcupine* of part of the North Atlantic, I could not detect the slightest trace of any vegetable organism at a greater depth than fifteen fathoms. Animal organisms of all kinds and sizes, living and dead, were everywhere abundant, from the surface to the bottom; and it might at first be supposed that such constituted the only food of the oceanic animals which were observed, some of them being zoophagons, others sarcophagons, none phytophagons. But inasmuch as all animals are said to exhale carbonic acid gas, and on their death the same gas is given out by their decomposition, whence do oceanic animals get that supply of carbon which terrestrial and littoral or shallow-water animals derive, directly or indirectly, from plants? Can any class of marine animals assimilate the carbon contained in the sea, as plants assimilate the carbon contained in the air?

Not being a physiologist, I will not presume to offer an opinion; but the suggestions or questions which I have ventured to submit may perhaps be worth consideration. At all events the usual theory, that all animals ultimately depend for their nourishment on vegetable life, seems not to be applicable to the main ocean, and consequently not to one-half of the earth's surface.

J. GWYN JEFFREYS

GOLD DIGGERS IN THIBET

THE Thibetan gold-field of Thok-Jalung in lat. 32° 24′ 26″ and long. 81° 37′ 38″ was visited by the pundits employed by the G. T. Survey, in 1867 (August). The camp was pitched in a large desolate plain of a reddish brown appearance, the tents stand in pits seven or eight feet deep for protection against the cold wind, the elevation being 16,330 feet, yet the diggers prefer to work in the winter, when nearly 600 tents are to be found there; the soil when frozen does not "cave in." They have no wood, but use dried dung for fuel, and the water is so brackish as to be undrinkable until frozen and remelted. They live well, taking three meals a-day of boiled meat, barley cakes, and tea stewed with butter. They will not use the Himalayan tea, as too heating and only fit for poor folks.

The gold is obtained from an excavation a mile long, twenty-five feet deep, and ten to two hundred paces wide, through which a small stream runs; the implements used are a long-handled kind of spade, and an iron hoe.

The water is dammed up, and a sloping channel left; at the bottom a cloth is spread, kept down by stones so as to make the bottom uneven; one man sprinkles the auriferous earth over the channel, and another flushes the channel by means of a leather bag, the pieces of gold fall into the inequalities and are easily collected in the cloth by lifting up the stones. The yield is large, nuggets of two pounds weight are found; the gold sells on the spot at rather less than thirty rupees per ounce. A gold commissioner or "sarpon" superintends all the goldfields, a string of which extends along the northern watershed of the Brahmaputra, from Lhasa to Rudok. Each field has a chief or master, but anyone may dig who pays the annual licence-fee of one sarapoo or two-fifths of an ounce.

The curious posture for sleeping, universal among the Thibetans, was observed here. They invariably draw their knees close up to their heads, and rest on their knees and elbows, huddling every scrap of clothing they can muster on their backs; the richer rest thus on a mattress rising towards the head. The poorer avail themselves of a suitable slope on the hill side, or pile stones and earth to a convenient height. This position is most probably adopted in order to secure as much warmth as possible for the abdomen, the thighs pressing against it and excluding the air.

The gold-diggers recreate themselves with tobacco smoked in iron pipes, and, notwithstanding the hardships of their laborious toil, seem very merry, singing songs in chorus, in which the women and children join.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents.*]

Lectures to Ladies

YOUR correspondent "M." in her letter, which appeared in NATURE No. IV., on the subject of the exclusion of teachers from the lectures to ladies at South Kensington and University College, is scarcely just in her remark that "at University College they don't pretend to care for such an audience." The committee of the Educational Association certainly do not *pretend* to care for governesses, but give a more substantial proof of their care by admitting them on reduced terms.

All honour to "M." for advocating the claims of governesses; but has she not, in her desire for improving their mental faculties, omitted to take an account of their physical powers? To the question, therefore, which she has propounded—"How can any one who is hard at work all day go to a lecture in the forenoon?"—I am tempted to reply, in the American fashion, by asking another: "How can any one who is *hard* at work all day go to a lecture in the evening?" There is also the minor consideration that the hire of a lecture-room (the majority of our classes being held in a hired room) for the evening is nearly twice that of a room for the morning, so that it would be a somewhat hazardous experiment to institute evening classes on the chance of ladies who are engaged in teaching all day attending in sufficient numbers to pay the rent.

In conclusion, I hope that if "M." can spare a few minutes of her valuable time some forenoon, she will look in at one of our lectures; and if she sees, or rather hears, anyone answering the description of "Lady Barbara, who sneers aloud," I will use my utmost endeavours to get up an evening class for "M." even though she should be the only pupil.

THE HON. SEC. OF THE LADIES' EDUCATIONAL ASSOCIATION, LONDON

Chrysophanus Dispar

YOU ask for information about *Chrysophanus Dispar*. The statement that it has been met with in Kerry is not in itself improbable, and entomologists will be interested in having it confirmed; but when we find it said in the same paragraph that the insect is not uncommon in England, it will be received with doubt. *C. Dispar* has hitherto been found in only one locality in these islands, the neighbourhood of the fens formerly surrounding Whittlesea Mere. Other localities appear in works on entomology, but have never been authenticated. Owing partly to the drainage of the fens, and partly to the indefatigable efforts of dealers and other collectors, the insect has been quite extinct, I believe, for nearly twenty years.

Of late years the subdivision of species in entomology as well as in other departments of Natural History has been somewhat checked. What formerly appeared as those distinct species of *Polyommatus*, in our books of British Butterflies, under the names of Agestis, Artaxerxes, and Salmacis, are now all referred to the first-named species. Agestis is absent where Salmacis is found, and both where Artaxerxes is found, and the variety is referred to the difference of latitude. In the same way entomologists no longer recognise any specific distinction between *C. Dispar* and *C. Hippothoe*, widely-spread continental species. I possess a fine series of *C. Dispar* reared from larvæ taken in the year 1846. The spot in which they were found is close to the Holme station, 69 miles from London on the Great Northern Railway. They fed exclusively on the common water dock (*Rumex Palustris*). It is a curious illustration of the obscure causes which regulate the geographical range of species, that though the plant is abundant in the whole range of fen country, and generally throughout England, the butterfly was always confined to that immediate neighbourhood.

C. Virgaureæ was introduced into catalogues of British Lepidoptera on the authority of dealers, but its claims to be a British species were never authenticated.

Eton, Windsor. C. W. D.

The Brighton Aquarium

WOULD it be unduly troubling you were I to ask you to inform me, throug the medium of the columns of NATURE, if the much-talked-of Brighton Aquarium is really to be "started"?

H. H. MOTT

The Cloaca Maxima

WILL you pardon me for asking a question which probably I ought to be able to answer myself? Mr. Corfield, in his interesting comparison of the hygienic performances of the ancients and ourselves, mentions the well-known Cloaca Maxima as one of the great glories of the Romans. Can he tell us how they got the sewage into it? I presume the invention of Bramah was not known in those times, and I was a little disappointed in not finding in his able paper a solution of a mystery which has puzzled me since my childhood. What did the Romans want with a Cloaca Maxima, and how did they use it?

Dec. 11th. IGNORAMUS

Lightning in a Clear Sky

THE following extract from the "Life of Charlemagne," by Eginhard, a contemporary, may be interesting to C. W. D. "Cum Carolus imperator ultimam in Saxoniam expeditionem contra Godefridum, regem Danorum, ageret, quadam die, cum, ante exortum solis, castris egressus, iter agere cœpisset, vidit repente delapsam cœlitus cum ingenti lumine facem a dextra in sinistram per serenum aera transcurrere; cunctisque hoc signum, quid portenderet, admirantibus, subito equus quem sedebat, capite deorsum merso, decidit, eumque tam graviter ad terram elisit, ut fibula sagi rupta balteoque gladii dissipato, a festinantibus qui aderant ministris exarmatus non sine adminiculo levaretur. Jaculum etiam quod tunc forte manu tenebat, ita elapsum est ut viginti vel eo amplius pedum spatio longe jaceret." J. M. W.

NOTES

IT is stated that the Council of the British Association for the Advancement of Science have determined to ask the permission of the Lord President of the Council to appear before him as a Deputation, to urge upon the Government the need of a Royal Commission to inquire into the Present State of Science in England. We may congratulate ourselves that in Lord De Grey we have a Minister whose well-known large and scientific sympathies ensure a careful consideration of the important proposition to be laid before him.

MOST of our readers know ere this that the Government has determined not to fill up the appointment of the Mastership of the Mint vacant by the death of the lamented Graham. The duties are to be performed by Mr. Freemantle, who deserves all praise for what he has done; and the Mint is, for the future, to be looked upon as an outpost of the Treasury. One hoped, seeing how rare are the scientific rewards in England, that a post that had been held by a Newton, a Herschel, and a Graham, might have been left as it was; but we hear that the Government have, in this case, some real justification for what they have done. In fact, it is the tendency shown by this action—a tendency to cut down everything, especially everything scientific—and not the action itself, which is more in question.

THERE is more and later news from Livingstone, who, judging from his letter to Dr. Kirk, published in the journals, is still weak in health. All we need give is his own idea of the work he has yet to accomplish:—"As to the work to be done by me, it is only to connect the sources which I have discovered from 500 to 700 miles south of Speke and Baker's with their Nile. The volume of water which flows north from latitude 12° south is so large, I suspect I have been working at the sources of the Congo as well as those of the Nile. I have to go down the eastern line of drainage to Baker's turning point. Tanganyika, Nyige Chowambe (Baker's?) are one water, and the head of it is 300 miles south of this. The western and central lines of drainage converge into an unvisited lake west or south-west of this. The outflow of this, whether to Congo or Nile, I have to ascertain. The people of this, called Manyema, are cannibals, if Arabs speak truly. I may have to go there first, and down Tanganyika, if I come out uneaten, and find my new squad from Zanzibar."

WE take a remarkable instance of resolute self-sacrifice from Mr. Hayward's account of the Turki rebellion against the Chinese dominion in 1863:—The Chinese garrison was shut up in the fort of Yarkand, and for 40 days besieged by the Turki army: the only terms offered were that all should embrace Islam. The old Amban—the Chinese Viceroy of Turkestan—summoned his officers to a council, held in an upper room, the lower room was piled with barrels of gunpowder, with a train leading from beneath the chair of state. The officers assembled, wrangling about the probable ransom that would be taken. The Amban's sons moved among them, offering tea and sweetmeats, his daughters knelt weeping by his side, he himself sat calmly smoking his long pipe. Suddenly cannon shots were heard, and the shouts of Allah Akhbar announced the advance of the enemy to storm. A hint of the Amban's resolution spread among the assembly, amidst the confusion he spoke a short farewell, and calmly turning his pipe-bowl, shed the embers on the train—and all was over.

WE learn that the account of Professor Jacobi's new process for the electro-deposit of iron, which has recently appeared in this country, does not include several improvements of great scientific interest which have recently been developed, an account of which we hope shortly to give.

THE following notice has been issued by desire of the Lord Chancellor:—"The electors to the Savilian Professorship—namely, the Archbishop of Canterbury, the Lord Chancellor of Great Britain, the Chancellor of the University of Oxford, the Lord Bishop of London, the Secretary of State for the Home Department, the Lord Chief Justices of the Queen's Bench and Common Pleas, the Lord Chief Baron of the Exchequer, the Dean of the Arches, and the Warden of New College (who may, if it be their pleasure, call into council the Vice-Chancellor of the University of Oxford)—will proceed to the election of a Savilian Professor on Thursday, the 10th day of February, 1870, or as soon thereafter as may be. All candidates are required to be of the full age of 26 years, and, if Englishmen, to be Masters of Arts at the least. The other regulations respecting the Savilian Professor may be seen in the University Statute sanctioned by Her Majesty the Queen in the year 1858. Candidates are to send their applications, addressed to Gordon Whitbread, Esq., 31, Great George Street, Westminster, S.W., on or before the 24th of January, 1870."

Here is another note from Oxford:—The examiners for the Radcliffe Travelling Fellowship—Dr. Acland, Dr. Rolleston, and Sir B. C. Brodie—have given notice that the next examination for a Fellowship will commence on Monday, January 31, at 10 a.m. Candidates are requested to send their names on or before Wednesday, January 19, by letter addressed to the Regius Professor of Medicine, Museum, Oxford.

THE exploration of the caves at Wellington, in the western district of New South Wales, under the direction of Mr. Krefft and Dr. A. M. Thomson, is making good progress, and many remains of extinct animals, some of which are new to science, have been discovered. A trial shaft is already put down in the centre of the Breccia cave, to the depth of fifteen feet, and bones are still found at that depth.

As already stated in this journal, the University of Edinburgh has just made arrangements to enable ladies who wish to do so to study medicine. Those who avail themselves of the opportunity are taught in separate classes from those of the other medical students, each Professor at the University holding one class for men and another for women. Five lady students have already presented themselves for the medical matriculation examination. In London there is a "Female Medical Society," under the presidency of the Earl of Shaftesbury. The objects of the Female Medical Society are—"1. To promote the employment of properly educated women in the practice of midwifery, and the treatment of the diseases of women and children. 2. To provide educated women with proper facilities for learning the theory and practice of midwifery, and the necessary branches of medical science." To carry out these objects, the Society established a "Ladies' Medical College" five years ago, and eighty-two ladies have during that period availed themselves of the facilities it offered; most of them have since started in business, and are succeeding admirably.

DR. PETERMANN, of Gotha, the well-known German geographer, publishes an interesting article in the *Cologne Gazette* on the mission of Dr. Nachtigal to Central Africa. The latter was sent by the King of Prussia, on the 18th of February, 1869, to present Sultan Scheick Omar with some valuable gifts from King William, in recognition of the friendly reception given by the Sultan, in 1866, to Herr Gerhard Rohlfs and Herr Von Beuermann, an officer of the Prussian army. Dr. Nachtigal proceeded to Mursuk (near which place Miss Tinné was murdered), but finding that there was no prospect at present of reaching Bornu in safety, he proceeded on an expedition to Tibesti, in the Tibbu country, leaving the presents at Mursuk. Similar expeditions, says Dr. Petermann, have been undertaken by various eminent travellers during the last fifty years. In 1820 the Tibbu country was visited by Lyon; in 1822 by Denham, Clapperton, and Oudney; in 1853 by E. Vogel; in 1855 by Dr. Barth; in 1862 by Herr Von Beuermann; and in 1866 by Gerhard Rohlfs. Most of these attempted to go through Tibesti, but without success; and Dr. Nachtigal is the only European who has ever accomplished this dangerous feat. He left Mursuk on the 6th of June last, and returned on the 8th of October, after a series of wonderful adventures and escapes, which are related in a report addressed by him to Dr. Petermann, and now in the press.

THE Weekly Bulletin of the Scientific Association of France, dated the 12th instant, contains letters from Algeria recording a series of violent earthquake shocks experienced at Biskra, Seriana, and Sidi Okba, in the Province of Constantine. The disturbances extended from the 16th to the 19th of November, and appear to have been of a very alarming character. The fact that no great damage was done to buildings is ascribed to the movement being chiefly vertical. The horizontal direction is stated by an observer to be from south-west to north-east, and by another from north-east to south-west.

SCHOPENAUER'S treatise on the "Philosophy of vision and colours," which originally appeared upwards of fifty years ago, and which has hitherto been treated with unmerited neglect by the great writers on physiological optics, has just reached a third edition. An interleaved and annotated copy of the second edition prepared by the author himself in 1854 was found amongst his papers, and has formed the basis for the present "improved and augmented" reissue, which appears under the editorship of Julius Frauenstädt.

WE desire to call special attention to the singularly interesting address of the new Rector of the University of Vienna, Carl von Littrow, on a subject which does not at first sight appear to be of a very interesting character, viz., the backwardness of the ancients in the sciences. This backwardness he ascribes, firstly, to an actual want of the power of accurate observation; and, secondly, to a restless spirit of speculation. The illustrations of these positions are drawn from astronomy, the science to which in early times the greatest care was devoted. Of the instances adduced to show that the ancients, notwithstanding their fine feeling for form, evidenced in the remains of classic art, had not even the most primitive power of observation, we may mention the following. According to the elder Pliny, whose estimate is very much higher than those of Hipparchus and Ptolemy as recorded in the Almagest, the number of fixed stars is 1,600; whereas, in our own day, Argelander, working in such a comparatively unfavourable climate as Bonn, records on his maps no less than 3,256 stars visible to the naked eye. Again, Argelander gives nineteen as the number of nebulæ and star-clusters visible in our latitudes, while Hipparchus mentions only two, and Ptolemy but five; both of these observers entirely passing over such remarkable objects as the nebulæ in Orion and in Andromeda. The group of the Pleiades was considered of great importance for ancient navigation, and was constantly watched; and yet only seven of its stars were discovered. Indeed most of the early observers could only see six; the seventh was lost sight of for centuries; and ultimately, when the middle star in the tail of the Great Bear first attracted attention, the conclusion arrived at was that the latter was the missing seventh star of the Pleides. Nowadays cases are known of people who are not astronomers seeing from fourteen to sixteen stars in the Pleiades; and it is by no means uncommon for persons of good sight to see eleven. The star α in Capricornus was seen by man for thousands of years without its being noted that it is a double star, a fact that any child would discover now if its attention were directed to it. It would be interesting to know what is the capacity of individuals of savage races as regards discriminating celestial objects. Light might then be thrown upon the question, how far the observational defects of the early astronomers were due to mere carelessness, and how far we inherit a schooled eye from generations of ancestors who gradually accustomed themselves to the accurate discrimination of external objects.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 9.—Dr. W. A. Miller, V.P., in the chair. The following papers were read:—

"Spectroscopic Observations of the Sun."—No. V. By J. Norman Lockyer, F.R.S.

The author first referred to several new facts of importance as follows:

"I. The extreme rates of movement in the chromosphere observed up to the present time are—

Vertical movement	40 miles a second
Horizontal or cyclonic movement .	120 ,,

"II. I have carefully observed the chromosphere when spots have been near the limb. The spots have sometimes been accompanied by prominences, at other times they have not been so accompanied. Such observations show that we may have spots visible without prominences in the same region, and prominences without spots; but I do not say that a spot is not accompanied by a prominenee *at some stage of its life*, or that it does not result from some action which, in the majority of cases, is accompanied by a prominence.

"III. At times, when a prominence is seen bright on the sun itself, the bright F line varies considerably, both in thickness and brilliancy, within the thickness of the dark line. The appearances presented are exactly as if we were looking at the prominences through a grating.

"IV. Bright prominences, when seen above spots on the disk, if built up of other substances besides hydrogen, are indicated by the bright lines of those substances in addition to the lines of hydrogen. The bright lines are then seen very thin, situated centrally (or nearly so) on the broad absorption-bands caused by the underlying less-luminous vapours of the same substances.

"V. I have at last detected an absorption-line corresponding to the orange line in the chromosphere. Father Secchi states* that there is a line corresponding to it much brighter than the rest of the spectrum. My observation would seem to indicate that he has observed a bright line less refrangible than the one in question, which bright line is at times excessively brilliant. It requires absolutely perfect atmospheric conditions to see it in the ordinary solar spectrum. It is best seen in a spot-spectrum when the spot is partially covered by a bright prominence.

"VI. In the neighbourhood of spots the F bright line is sometimes observed considerably widened out in several places, as if the spectroscope were analysing injections of hydrogen at great pressure in very limited regions into the chromosphere.

"VII. The brilliancy of the bright lines visible in the ordinary solar spectrum is extremely variable. One of them, at 1871·5, and another, at 1529·5 of Kirchhoff's scale, I have detected in the chromosphere at the same time that they were brilliant in the ordinary solar spectrum.

"VIII. Alterations of wave-length have been detected in the sodium-, magnesium-, and iron-lines in a spot-spectrum. In the case of the last substance, the lines in which the alteration was detected were *not* those observed when iron (if we accept them to be due to iron alone) is injected into the chromosphere.

"IX. When the chromosphere is observed with a tangential slit, the F bright line close to the sun's limb shows traces of absorption, which gradually diminish as the higher strata of the chromosphere are brought on to the slit, until the absorption-line finally thins out and entirely disappears. The lines of other substances thus observed do not show this absorption.

"X. During the most recent observations, I have been able to detect traces of magnesium and iron in nearly all solar latitudes in the chromosphere. If this be not merely the result of the good definition lately, it would indicate an increased general photospheric disturbance as the maximum sunspot period is approached. Moreover, I suspect that the chromosphere has lost somewhat of its height."

The author appends a list of the bright lines, the position of which in the chromosphere have been determined absolutely, with the dates of discovery, remarking that in the case of C and F his observations were anticipated by M. Janssen:—

? band or line near black line, very delicate . . .	2054·0.	July 5.

Other lines besides these have been seen at different times; but their positions have not been determined absolutely.

The author points out that taking iron as an instance, and assuming that the iron-lines mapped by Ångström and Kirchhoff are due to iron only, he has only been able, up to the present time, to detect three lines out of the total number (460) in the spectrum of the lower regions of the chromosphere,—a fact full of promise as regards the possible results of future laboratory work. The same remark applies to magnesium and barium.

The paper then proceeded as follows:—

"Dr. Frankland and myself have determined that the widening out of the sodium-line in the spectrum of a spot which I pointed out in 1866, and then stated to be possibly an evidence of greater absorption, indicates a greater absorption due to greater pressure.

"The continuous widening out of the sodium-line in a spot must therefore be regarded as furnishing an additional argument (if one were now needed) in favour of the theory of the physical constitution of the sun first put forward by Dr. Frankland and myself—namely, that the chromosphere and the photosphere form the true atmosphere of the sun, and that under ordinary circumstances the absorption is continuous from the top of the chromosphere to the bottom of the photosphere, at whatever depth from the bottom of the spot that bottom may be assumed to be.

"This theory was based upon all our observations made from 1866 up to the time at which it was communicated to the Royal Society and the Paris Academy of Sciences, and has been strengthened by all our subsequent work; but several announcements made by Father Secchi to the Paris Academy of Sciences and other learned bodies are so opposed to it, and differ so much from my own observations, that it is necessary that I should refer to them, and give my reasons for still thinking that the theory above referred to is not in disaccord with facts.

"Father Secchi states that the chromosphere is often separated from the photosphere, and that between the chromosphere and the photosphere there exists a stratum giving a continuous spectrum, which he considers to be the base of the solar atmosphere, and in which he thinks that the inversion of the spectrum takes place.

"With regard to the first assertion, I may first state that all the observations I have made have led me to a contrary conclusion. Secondly, in an instrument of comparatively small dispersive power, such as that employed by Father Secchi, in which the widening out of the F line at the base of the chromosphere is not clearly indicated, it is almost impossible to determine, by means of the spectroscope, whether the chromosphere rests on the sun or not, as the chromosphere is an envelope and we are not dealing merely with a section. But an instrument of great dispersive power can at once settle the question; for since the F line widens out with pressure, and as the pressure increases as the sun is approached, the continuous curvature of the F line must indicate really the spectrum of a section; and if the chromosphere were suspended merely at a certain height above the photosphere, we should not get a widening due to pressure: but we always do get such a widening.

"With regard to the second assertion, I would remark that if such a continuous-spectrum-giving envelope existed, I entirely fail to see how it could be regarded as a region of selective absorption. Secondly, my observations have indicated no such stratum, although injections of sodium, magnesium, &c. into the chromosphere not exceeding the limit of the sun's limb by 2″ have been regularly observed for several months past. To-day I have even detected a low level of barium in the chromosphere not 1″ high. This indicates, I think, that my instrument is not lacking in delicacy; and as I have never seen anything approaching to a continuous spectrum when my instrument has been in perfect adjustment, I am inclined to attribute the observation to some instrumental error. Such a phenomenon might arise from a local injection of solid or liquid particles into the chromosphere, if such injection were possible. But I have never seen such an injection. If such an occurrence could be observed, it would at once settle that part of Dr. Frankland's and my own theory, which regards the chromosphere as the last layer of the solar atmosphere; and if it were possible to accept Father Secchi's observation, the point would be settled in our favour.

"The sodium experiments to which I have referred, however, and the widening out of the lines in the spot-spectra, clearly indicate, I think, that the base of the atmosphere is below the spot and not above it. I therefore cannot accept Father Secchi's statement as being final against another part of the theory to which I have referred—a conclusion which Father Secchi himself seems to accept in other communications.

"Father Secchi remarks also that the F line is produced by the absorption of other bodies besides hydrogen, because it never disappears. This conclusion is also negatived by my observations; for it has very often been observed to disappear altogether and to be replaced by a bright line. At times, as I pointed out to the Royal Society some months ago, when a violent storm is going on accompanied by rapid elevations and depressions of the prominences, there is a black line on the less-refrangible side of the bright one; but this is a phenomenon due to a change of wave-length caused by a rapid motion of the hydrogen.

"With regard to the observation of spot-spectra, I find that every increase of dispersive power renders the phenomenon much more clear, and at the same time more simple. The selective absorption I discovered in 1866 comes out in its most intense form, but without any of the more complicated accompaniments described by Father Secchi. I find, however, that by using three prisms this complexity vanishes to a great extent. We get portions of the spectrum here and there abnormally bright, which have given rise doubtless to some of the statements of the distinguished Roman observer; but the bright lines, properly so-called, are as variable as they are in any other part of the disk, but not much more so. I quite agree that the 'interpretation' of sun-spot phenomena to which Father Secchi has referred,* which ascribes the appearances to anything but selective plus general absorption, is erroneous. But as I was not aware that it had ever been propounded, I can only refer to my own prior papers in support of my assertion which were communicated to the Royal Society some three years ago."

"Researches on Gaseous Spectra in relation to the Physical Constitution of the Sun, Stars, and Nebulæ."—Third Note. By E. Frankland, F.R.S., and J. Norman Lockyer, F.R.S.

The authors remark that it has been pointed out by Mr. Lockyer that the vapours of magnesium, iron, &c., are sometimes injected into the sun's chromosphere, and are then rendered sensible by their bright spectral lines. (Proc. Roy. Soc., vol. xvii. p. 351.)

2. It has also been shown (1) that these vapours, for the most part, attain only a very low elevation in the chromosphere, and (2) that on rare occasions the magnesium vapour is observed like a cloud separated from the photosphere.

3. It was further established on the 14th of March, 1869, and a drawing was sent to the Royal Society indicating, that when the magnesium vapour is thus injected, the spectral lines do not all attain the same height.

Thus, of the b lines, b^1 and b^2 are of nearly equal height, but b^4 is much shorter.

4. It has since been discovered that of the 450 iron lines observed by Ångström, only a very few are indicated in the spectrum of the chromosphere when iron vapour is injected into it.

5. The authors' experiments on hydrogen and nitrogen enabled them at once to connect these phenomena, always assuming that the great bulk of the absorption to which the Fraunhofer lines are due takes place in the photosphere itself.

It was only necessary, in fact, to assume that, as in the case of hydrogen and nitrogen, the spectrum became simpler where the density and temperature were less, to account at once for the reduction in the number of lines visible in those regions where, on the authors' theory, the pressure and temperature of the absorbing vapours of the sun are at their minimum.

6. It became important, therefore, to test the truth of this assumption by some laboratory experiments, the preliminary results of which are communicated in this note.

* *Comptes Rendus*, 1869, 1 sem. p. 764.

The spark was taken in air between two magnesium poles, so separated that the magnesium spectrum did not extend from pole to pole, but was visible only for a little distance, indicated by the atmosphere of magnesium vapour round each pole.

The disappearance of the *b* lines was then examined, and it was *found that they behaved exactly as they do on the sun.* Of the three lines, the most refrangible was the shortest; and shorter than this were other lines, *which Mr. Lockyer has not detected in the spectrum of the chromosphere.*

This preliminary experiment, therefore, quite justified the assumption, and must be regarded as strengthening the theory on which the assumption was based, namely, that the bulk of the absorption takes place in the photosphere, and that it and the chromosphere form the true atmosphere of the sun. In fact, had the experiment been made in hydrogen instead of in air, the phenomena indicated by the telescope would have been almost perfectly reproduced; for each increase in the temperature of the spark caused the magnesium vapour to extend further from the pole, and where the lines disappeared a band was observed surmounting them, which is possibly connected with one which at times is observed in the spectrum of the chromosphere itself when the magnesium lines are not visible.

Professor Williamson communicated a paper "On the successive Action of Sodium and Iodide of Ethyl on Acetic Ether," by J. Alfred Wanklyn, F.C.S. The author referred to a paper by Frankland and Duppa, describing the products obtained on treatment with iodide of ethyl of the yellow wax-like mass given by the action of sodium on acetic ether. Besides the description of the compounds, Frankland and Duppa gave four equations expressive of their view of the origin of the wax-like mass: each one of these four equations affirmed the evolution of an equivalent of hydrogen by every equivalent of sodium employed; but according to Mr. Wanklyn neither acetic ether nor any other ether ever evolves hydrogen by reaction with the alkali metals. All equations which assume evolution of hydrogen in these reactions are therefore inadmissible. In the present paper Mr. Wanklyn offers an explanation of Frankland and Duppa's products, which does not involve the assumption of evolution of hydrogen. On reference to Frankland and Duppa's paper just cited, it will be found that the products described by them as obtained from the "wax-like mass" and iodide of ethyl are the following:—

A. $C_8\ H_{14}\ O_3$, liquid boiling at 195° C.,

B. $C_{10}\ H_{18}\ O_3$, liquid boiling at 210° C. to 212° C.,

butyric ether, caproic ether, and also some unacted-upon acetic ether, and a considerable quantity of common ethylic ether. Mr. Wanklyn has already shown that the direct products of the action of sodium on acetic ether are ethylate of sodium and sodium-triacetyl. Nothing else seems to be produced directly. But the excess of acetic ether, which is necessarily taken, acts on some of the ethylate of sodium, producing alcohol and acetate of ethylene-sodium, the extent to which this secondary action takes place being determined by the exact circumstances of the experiment. We have, therefore, in the wax-like mass got by prolonging the action of sodium on acetic ether:—

Ethylate of sodium	$C_2\ H_5\ NaO$
Sodium-triacetyl	$C_6\ H_9\ O_3\ Na$
Acetate of ethylene-sodium . . .	$C_4\ H_7\ Na\ O_2$
Alcohol	$C_2\ H_6\ O$.

On the first three iodide of ethyl acts, giving iodide of sodium and organic liquids. From the ethylate of sodium comes the common ether. From the sodium-triacetyl comes ethyl-triacetyl, which is $A = C_8\ H_{14}\ O_3$, having been got by Geuther from the pure sodium-triacetyl. From isolated acetate of ethylene-sodium and iodide of ethylene Mr. Wanklyn has recently obtained liquid B, $C_{10}\ H_{18}\ O_3$. This liquid boiled at 212° C. and gave carbonate of baryta with baryta-water, and was identical with Frankland and Duppa's liquid B. By the action of liquid A upon ethylate of sodium Geuther has recently shown that butyric ether is produced together with acetate of ethylene-sodium, and Mr. Wanklyn predicts that liquid B will give caproic ether by a similar reaction.

Royal Geographical Society, December 13, Sir R. Murchison in the chair. The President made some comments on the recent letter from Dr. Livingstone, whose return would, he thought, very probably be delayed by the exploration of the waters, which might prove the head waters of the Congo. The paper of the evening was Mr. Hayward's account of his visit to Eastern Turkestan; a large map constructed by Captain George, from the maps and observations sent home by Mr. Hayward, and two views, enlarged from sketches taken by him on the spot, illustrated the paper. Dr. Leitner's collection of Yarkandi manufactures was also exhibited, and the presence of Niaz Muhammed, the native of Yarkand, excited much interest. Mr. Hayward has carefully fixed all the positions in the maps sent home by him, and also sent itineraries, list of names, and plans of towns. He mentioned the valuable pocket artificial horizon invented by Captain George, which enabled him to escape suspicion. Mr. Hayward left Leh Sept. 29, and proceeded by the Chang Chennoo Pass, 18,839 feet high, to Shadula, in lat. N. 36° 21′ 11″, long. E. 78° 18′, 360 miles from Leh, the frontier fort of Eastern Turkestan, 14,745 feet high, which is divided from the dominions of the Maharajah of Kashmir by the Karakorum range. Mr. Shaw had, unknown to Mr. Hayward, arrived a few days before. The travellers were detained while a messenger was sent forward to obtain permission for them to enter the country. The opportunity was taken to explore the sources of the Yarkand Daria, beyond the Khirgiz Pass, 17,095 feet high. From this a view of the Eastern Kuen Luen peaks was obtained, 90 miles away, the course of the river was traced and positions proved. A new pass, called the Yangi Pass, over the Kuen Luen, was observed, and described as practicable for horses, and easily made practicable for carriages, and even for guns. It is at present exposed to the depredations of robbers from Hunza Nagyr, which render it insecure and little used. Twenty days were spent in this exploration, and 300 miles of mountain districts explored. One peak rising to 28,278 feet, was observed from a spur of Kuen Luen Mountains. The source of the Yarkand River, in lat. 35° 37′ 34″ N., long. 77° 50′ E., was reached on December 8th. At a height of 16,654 feet above the sea, the cold experienced was intense. The thermometer the following morning showed the mercury to have sunk to a level with the bulb, or 18° below zero. Having returned to Shadula, he found that permission had come for his advance to Yarkand, and started on December 18th to reach that place by the Sanju Pass. Mr. Hayward described the Khirgizes, the Bedouins of Turkestan, from whom he experienced kindness and hospitality, as throughout the country seems to have been the case. From Shadula yaks were provided, on which the travellers crossed the Sanju Pass. The first village entered was Kibriz. The Turhi villages present a comfortable appearance. The country is well cultivated, and the people well to do. The dress, &c., of the different classes was carefully described. Slaves are still owned by some; but the former slave trade at Yarkand has been suppressed by Yakoob Kushbegi. Between Sanju and Yarkand a sandy steppe was crossed, the commencement of a desert called Tahla Makân Desert, stretching to the east, towards the Gobi Desert. Strange legends of former cities, now buried in the sand, were related by the Panja Bashi. Yarkand was entered on December 27th. It is described as a parallelogram of 2 miles by 1½, containing 40,000 houses, 120 mosques, and 120,000 inhabitants. It is defended by mud walls 45 feet high, with bastions, and an outlying fort. The ruler of Yarkand, Muhammed Yakoob (Kushbegie), "Atalih Ghazee" of Eastern Turkestan, was at his camp near Kashkar. The governor of the city, "a well-informed, pleasant, well-read man," received Mr. Hayward with much courtesy. A house was assigned him, and plentiful supplies furnished him; but he was not allowed, except on visits to the governor, to leave the courtyard of his house during the two months he remained in Yarkand.

February 24th, Mr. Hayward proceeded to Kashkar, which is a strong town of 60,000 to 70,000 people, the central point of all the Central Asia roads. The next day he was received by the ruler, who by his bravery and military talents has raised himself to the chief authority over Eastern Turkestan. His character and abilities impressed Mr. Hayward so much, that he says, were Central Asia undisturbed by foreign pressure, he would be another Zenghis Khan. He received the traveller kindly, and spoke of his desire for visits from Englishmen, who had been hitherto prevented from visiting his country by the Bokhara tragedy. He also alluded to the death of Adolph Schlagintweit, but did not mention that he had himself killed Hullee Khan, the murderer of Schlagintweit, two years ago. Mr. Hayward remained a month in Kashkar, vainly hoping to get permission to proceed to the Pamir Steppe, but was obliged to abandon the attempt. The position of Kashkar was fixed by him at

City . . . . . 39° 19′ 37″ } N. lat.
Fort . . . . . 39° 23′ 9″ }

and 76° 10′ E. long., at an elevation of 4,165 feet. He concluded by some account of the revolt against the Chinese dominion, which, after lasting a hundred years, was overthrown in 1863; after which the present ruler, with his Uzbeg troops, defeated the Tunganis, and successively made himself master of the different places, and is now master of the country. But his tenure is precarious, and his fear of assassination causes him to change his apartment every hour during the night.—In the ensuing discussion, the president stated that, so far from Russia regarding our commercial entrance into Eastern Turkestan with jealousy, the Czar and Prince Gortschakoff had both assured Mr. Forsyth that so long as the Atalih Ghazee confined himself to the country south of the Tian Shan, Russia would not interfere with Eastern Turkestan.—The president also pointed out that Mr. Hayward's discoveries had confirmed A. von Humboldt's theory as to the salient points of the mountain systems of Central Asia. Mr. Hayward was about starting to explore the Pamir Steppe, by way of Ghilghit.—Sir H. Rawlinson mentioned that he was enabled to state that the Indian Government were about to arrange with the Maharajah of Kashmir, to send officers to survey the routes to the frontier of Turkestan; and intended afterwards to enter into negotiations with the Atalih Ghazee for the same purpose, as to the routes in his dominions. It is understood that Russia has not recognised the Atalih Ghazee, regarding him as a rebel against the empire of China—an ally of Russia.

Royal Microscopical Society, December 8.—The Rev. J. B. Reade, M.A., F.R.S., president, in the chair. Prof. Rymer Jones, F.R.S., read a paper on Deep-sea Dredgings from China and Japan. Professor Jones stated that he had recently received from Lieut. Ross, R.N. (grandson of Sir J. Ross), certain specimens of deep-sea dredgings, obtained at a depth of 1,080 fathoms, from the bottom of the sea near Fly Island, in the neighbourhood of Sandal-wood Island. After alluding to the theories which had until a recent period prevailed with respect to the depth at which animal life existed in the ocean, and to the researches and discoveries of Prof. Forbes, Sir. J. Ross, and Dr. Wallich, Prof. Jones proceeded to give a description of the contents of a phial (a small portion of the dredgings sent by Lieut. Ross), from which about a grain and a half of solid matter had been obtained. The first result of the microscopic examination of this matter was the discovery of a considerable quantity of silex, so finely triturated, however, as to be scarcely visible. The next discovery was a large number of sponge *spiculæ*; many of the spicules being sculptured in forms of the greatest beauty. Of these spicules there were 12 genera. Some 800 or 900 specimens of *Foraminifera* were next found, exhibiting nearly every form of the animal hitherto found in the bed of the Atlantic. A still more interesting discovery was that of 600 or 700 *Polycystinæ*; which differed from those found in Barbadoes, in this respect, that whereas the latter were usually brought up fractured and imperfect, the former were perfectly intact in all parts, displaying the most exquisite structures, and hundreds being clothed in thin soft covering. From this fact it might be argued that they had been taken from their ocean home alive, notwithstanding the immense pressure to which they are said to be subjected. There were also many species present which had not as yet received names from naturalists. Besides these, Prof. Jones had found a large number of shields of various shapes, resembling the *Diatomaceæ*; and of these there were not less than 300. Lastly, he had found diatoms themselves, more sparsely distributed, but of larger size than those usually coming under the notice of microscopists; and of these there were over fifty specimens. What larger animals lived at the bottom of the deep sea he could not say, but as there appeared to be abundant food for them, and as both Sir J. Ross and Dr. Wallich had found star-fishes in the respective localities dredged by them, it might be reasonably inferred that they abounded in the ocean bed, and that a most extensive fauna existed there as yet entirely undiscovered. The following papers, for want of time, were taken as read, viz.: "On the Stylet Region of the Ominontoplean Broboscis," by Dr. McIntosh, and "Organisms in Mineral Infusions," by C. Staniland Wake, F.A.S.L. Four gentlemen were elected Fellows, and the Society adjourned to January 12, 1870.

Entomological Society, December 9.—Mr. H. W. Bates, president, in the chair. Seven new members were elected, namely, MM. d'Emerich, De Marseul, and Oberthur (foreign members), Captain Lang, R.E., and Messrs. W. Arnold Lewis, J. Cosmo Melvill, and Howard Vaughan. Exhibitions of *Hymenoptera* were made by Prof. Westwood and Mr. Frederick Smith; of *Lepidoptera*, by Mr. F. Smith and Mr. J. Jenner Weir; of *Coleoptera*, by Prof. Westwood and Mr. Albert Müller. Communications were read from Mr. Robert McLachlan on *Boreus hymenalis* and *B. Westwoodii*; from Mr. Edwin Brown, respecting the locust captured at Burton-on-Trent and exhibited at the previous meeting, which had been identified as *Acridium peregrinum*, a species distributed over a great part of Asia and the North of Africa, but not hitherto detected in Europe.

Ethnological Society, December 7.—Prof. Huxley, LL.D., F.R.S., president, in the chair. At the meeting of the International Congress for Prehistoric Archæology, held last year at Norwich, a committee was formed, under the presidency of Sir John Lubbock, Bart., for the purpose of inquiring into the present condition of the prehistoric remains in the British Isles. Subsequently, the functions of this committee were transferred to the Ethnological Society, and the first-fruits of its labours in this direction have just appeared in the shape of a valuable Report on the Prehistoric Monuments of the Channel Islands, prepared by Lieut. Oliver, R.A. These islands are remarkably rich in megalithic structures of noble proportions, but from their unprotected state they have been subject to the most ruthless destruction. Not only have they been demolished by the "navvy" and the mere treasure-seeker, but they have also suffered considerably from injudicious attempts at restoration. Nevertheless, they are still sufficiently numerous to form the subject of an elaborate Report. Lieut. Oliver pointed out the resemblance between some of these megalithic monuments and those in Madagascar erected at the present day by the hill-tribes of Hovas. The Report was copiously illustrated, and called forth a discussion, in which the chief speakers were the president, Mr. J. Lukis, Mr. J. W. Flower, Dr. Hyde Clarke, and Col. Lane-Fox.—At the same meeting, a note was read from Mr. Acheson on a supposed stone implement, found beneath the bed of a river worked for gold in Co. Wicklow.—A communication was also made, by Maj.-General Lefroy, on the Stature of the North-American Indians of the Chipewyan Tribe; and remarks were made upon it by Dr. Richard King.

Anthropological Society, December 7.—Dr. Beddoe, president, in the chair. Dr. Leitner gave some further details of his visit to Dardistan in 1866, especially referring to the Shina race. He briefly touched upon the main outlines of his journey, mentioning that his experience had modified his views as to the inconvenience resulting from the rarefaction of the air at high altitudes, inasmuch as he and his companions had surmounted passes of 18,000 feet without experiencing any of the usual effects. Although the Dards were at war with the Maharajah of Kashmir, and the towns apparently deserted, he was able to assemble, by sending round a drummer, 150 to a feast, and continued on most friendly terms with them during his abode in Ghilghit. The vocabularies and grammars of the hitherto unwritten Dardoo dialects which he has collected show a probably parental Aryan type. It is to be much regretted that the refusal of the India Office to grant an extension of leave to Dr. Leitner will compel his return to India within a fortnight, and almost deprive him of the opportunity of arranging and comparing these hitherto unknown languages. The Indian Government does not seem desirous of encouraging acquaintance with Central Asia. A traveller desirous of penetrating by Ghilghit to the Panin Steppe had recently been refused mules. Several interesting particulars of the customs among the Chilasis Ghilghites and other Dards were mentioned, which are alien to Mahommedan and Hindu ideas. The place and privileges accorded to women, who receive the visits of their husbands' friends without any suspicion—the custom of courtship, the use of wine, the fondness for dogs,—all seem to point to an independent origin of religion and manners. The value set upon dogs was illustrated by the fact that two men-slaves were given as the price of a good hound. The Sooni ruler of Chitral not merely sold his subjects, but his own mother, as a slave, and when asked how he could sell her whose breasts had suckled him, pointed to a cow, and said that she gave him milk constantly, yet he would sell her! and when a Moollah, who was to be sold, threatened him with vengeance for selling a minister of the Word of God, he replied that everybody sold the Koran—why therefore should he not sell the expounder of it. Dr. Leitner stated that the Kafirs were certainly fairer than the Kashmiris, but his experience hardly bore out the statement of their being exceptionally fair, with blue eyes and light hair. West of Balti the general type of face approximated more to the European. He could discover no religion or rites among them, save that once a year each deposited a stone on a cairn, situated on a high mountain. He found a species of caste division among the

Shinas, but the different castes intermarry and eat together. He narrated a curious Shina legend of a Shinari who fell in with a company of one-eyed demons, and was a witness of a demoniacal wedding. A very numerous and interested assembly listened with marked approval; and in reply to various questions, Dr. Leitner further stated that he had not remarked any megalithic or Druidic remains. The countries were traversed by him rather with a view to linguistic and philological discoveries. The houses were meanly constructed; the food evinced a rough skill in cookery; every Dard family seemed to possess a cavern, the secret of which was known only to them, and they thus had plentiful supplies of food, which they shared with him, while the Maharajah's sepoys were starving. Strong opinions were expressed as to the refusal of extension of leave to Dr. Leitner, and a resolution was unanimously passed calling upon the Government to take measures to aid and encourage travellers to visit these little-known regions of Central Asia. It is to be hoped that some means may be found to prolong the visit of Niar Mahommed, the Yarkandi, and both obtain from him information, and give him lasting impression of our resources and hospitality. We should not omit to mention that Dr. Leitner altogether denied the statement quoted from the *Invalide Russe*, that he had visited Herat or taken part in the battle of Samarcand.

Philological Society, December 3.—Mr. A. J. Ellis, F.R.S., in the chair. Mr. A. Melville Bell read a paper on Pronouncing all Languages. He showed how all the vowels could be produced: first, by placing the tongue in nine different positions, by means of which the extent and form of the neck which unites the front with the back cavity of the mouth was modified; secondly, by increasing or diminishing the whole of the cavities behind this neck; thirdly and fourthly, by altering the form of the cavities in front of the neck in the two former cases, by the action of the lips. The thirty-six vowels thus produced practically covered all known vowel sounds. He also showed how the consonants could be produced by three positions of the tongue and one of the lips, modified in six definite manners, allowing voice or breath to pass through a simple narrow orifice with central aperture, or a compound orifice of the same description, or a double simple or compound orifice, the central passage being stopped, and emission of voice taking place at the sides; or else by stopping breath or voice altogether, or allowing them to pass through the nose. He also explained how these forty-eight consonants could be varied, producing, with the glottal and nasal actions, all the possible varieties of articulation. He illustrated his paper by diagrams and models of his symbols, by which in each case he made the precise position of the organs of speech necessary for producing each sound visible on paper in a single definite and intelligible letter. He informed the Society that these letters had been most effective in teaching little children who had been born deaf and dumb to articulate and distinguish vowel sounds with accuracy; a statement which the chairman confirmed from personal knowledge of Miss Hull's school for deaf and dumb girls, 102, Warwick Gardens, Kensington. The meeting unanimously passed the following resolution: "That this meeting of the Philological Society desires to express its strong sense of the beauty and great value of Mr. A. M. Bell's system of Visible Speech, and its ready applicability to purposes of philological investigation."

Institution of Civil Engineers, December 7.—Mr. C. W. Gregory, president, in the chair. The first paper read was on the Public Works of the Province of Canterbury, New Zealand, by Mr. Edward Dobson, Assoc. Inst. C.E. In this communication a history was given of the Public Works Department of Canterbury, from its establishment, in 1854, to the completion of the railways, in 1868. During that period the survey of the province, commenced under the "Canterbury Association," had been completed by the officers of the Survey Department; the eastern portion of the province had been thrown open to settlement, by the construction of many hundred miles of metalled roads; the western goldfields had been connected with the capital, by a coach-road through the passes of the New Zealand Alps—a road remarkable both for the boldness of its design and the circumstances under which it was executed; and a complete system of railroad had been surveyed, the key to which (a tunnel 129 chains in length through the crater wall of Lyttleton Harbour) had been successfully completed. Extensive harbour works had been constructed, public buildings erected in the principal towns, and telegraph and postal services carried to a fair state of organisation. The total expenditure on public works and surveys during the period referred to had been, in round numbers, 1,800,000*l.*, out of a total Government expenditure of about 8,880,000*l.* The population in 1854 was about 6,000; in 1868 it amounted to 54,000, including the mining population of the county of Westland. The great bulk of the public works of Canterbury possessed but little professional interest—the country being level, and the bridges chiefly of timber of ordinary construction. Many of the rivers run on ridges above the general surface of the plains, and in dealing with them it was essential to leave abundant waterway, as there was little chance of any ordinary embankment standing against such torrents as they sometimes carried. Paradoxical as it might appear, the portions of the proposed railways which were to traverse the level plains would require heavy earthworks, while the lines through the ranges, being contoured on the hill-sides, would be carried for miles on surface gradients with light side-cutting through a mountainous and difficult country. The principal works executed by the Government were: first, the Summer Road from Lyttelton to Christchurch, which was scraped out of the cliffs for a continuous length of several miles; second, the West Coast Road, from Christchurch to Hokitika, which was constructed in nine months, through a hundred miles of rough and difficult country, totally uninhabited, and for the most part densely timbered; third, the Moorhouse Tunnel, on the line of the Lyttelton and Christchurch Railway, 2,861 yards in length, driven through the crater of an extinct volcano under a summit level 1,220 feet above the sea; and fourth, the wharf and jetties at the Lyttelton station, built upon a soft mud-bank which was, in places, 50 feet in depth. In laying out roads on hilly ground, the principle uniformly adopted was to follow the windings of the spurs, contouring the gradients with the spirit-level, so as to minimize both cutting and embankment, and to dispense with culverts as far as possible. In the case of side cuttings, the gradient was contoured with the spirit-level and lock-spitted. The back line of the floor of the cutting was thus ranged out, and the depth of the cutting measured at every half-chain. The width of the slope was then calculated and set off, and the back line of the slope lock-spitted. The work could then be let by contract at any future time when the funds might be voted by the council, no plans or sections being required, or any details, beyond the rate of slope, the total length of the cutting, and its cubic content. A serious difficulty in the conduct of the road works was the want of timber. The expedient adopted was to keep constantly in stock a quantity of planks, 16 feet 8 inches long, and 8 inches by 3 inches in section, and the bridges and culverts were built on standard patterns designed with reference to this unit of material. This plan effected a great saving of office labour, as no drawings were required in ordinary cases; and as three planks made up 100 feet (board measure), any labourer was competent to take an account of the timber used, all that was necessary being to count the number of planks. Amongst the road bridges there were few that presented special interest, with, however, two exceptions. These were: first, a drawbridge over the Waimakariri River, built on the telescope principle, from a simple design, and which worked satisfactorily; and, secondly, a bridge over the Taipo River, on the West Coast Road, presenting several peculiarities of construction. The Harbour Works possessed considerable interest, which was enhanced by their partial failure. It was found that the mud-bank was too soft to support the screws of the screw-pile jetty, and, accordingly, additional lengths of piles were cast, and a solid core of hard wood placed in the bottom of each pile, and driven down to the solid rock, on which the weight of the structure was made to rest; the flanges of the screws simply acting as supports to check lateral vibrations. The diagonal bracing was put in by divers without difficulty, the exact length of each brace being taken from a template applied by the diver to the work after the piles were screwed down to their proper depth. The sea-wall slipped forward in two places during the progress of the work, the total amount of forward movement in each case being between 5 feet and 6 feet. The author did not consider that any advantage would have been gained by carrying the piles down to the solid rock, as, in all probability, the outward movement of the embankment would in that case have overturned the work and destroyed it. He thought that the partial failure of the work might be attributed to two causes: first, that the stone embankment was deficient, both in bulk and weight, for the duty it had to perform; and, secondly, that the tipping of the clay embankment was commenced before the stone embankment had had time to take a solid bearing, so as to form an abutment to resist the pressure of the backing. The work had since been completed, by driving an outer row of piles and putting in fresh capsills, jointing, and planking; and locomotives had been running for twelve months over the embankment without any further slipping, or more than the ordinary amount of settlement. It was worthy of notice, that no effect whatever was produced upon the sea-wall, or the jetties, by the great earthquake wave of August 16th, 1868, although the sea receded so as to lay dry a great portion of the harbour; and it might have been reasonably expected that the removal of the pressure upon the ground in front of the sea-wall would have been accompanied by the subsidence of the station ground. The breakwater was still in progress by prison labour.—The second paper, on Ocean Steam Navigation, with a view to its further Development, by Mr. John Grantham, Memb. Inst. C.E., was read in part, and it was announced that it would be resumed at the next meeting.

EDINBURGH

Naturalists' Field Club, November 30.—Annual Meeting. The retiring president, Mr. Brown, delivered an address on the Education and Ethics of a Naturalist.—The following officers were then elected for the ensuing session:—Mr. R. Scot-Skirving, president; Mr. A. Craig-Christie, vice-president; Mr. Andrew Taylor, Lecturer on Geology, hon. treasurer and secretary; Drs. Black, McBain, R.N., Richardson, and Cameron, and Messrs. Brown, Sadler, Jackson, Panton, C. W. Peach, Herbert (Trinity), Kannemyer, and Archer, council. The club recorded its thanks to Mr. Thomas Edmonston, the late secretary, for his services. Miss Phœbe Blyth, of Abbotsford Park, was admitted without a ballot, and on a ballot the following gentlemen were elected members:—Lieut.-Colonel Rankin (Trinity), Dr. H. W. Nachot, and Messrs. Leitch and Macfie. The annual dinner took place the same evening, the president in the chair.

DUBLIN

Royal Geological Society of Ireland, December 8.—On this date a joint meeting of the fellows of this society and of the fellows of the Royal Zoological Society was held in one of the lecture-rooms of Trinity College, Sir Dominic Corrigan, Bart., in the chair. The Rev. Prof. Haughton read a paper on the Comparative Mechanism of the Flexor Tendons of the Feet and Hands in Mammals, Birds, and Reptiles; Prof. Traquair read a paper on *Griffithides mucronatus*, McCoy.

Institution of Civil Engineers of Ireland, December 8.—Mr. J. Ball Greene, president, in the chair. Mr. J. Price read a paper by Mr. W. Anderson, one of the ex-presidents, entitled "Record of some Experiments on Heating Water and on Condensing Steam by tubular and double-cased vessels."

MANCHESTER.

Literary and Philosophical Society, November 16.—J. P. Joule, LL.D., F.R.S., president, in the chair. Professor Osborne Reynolds, B.A., of Owens College, was elected an ordinary member of the society. A communication by Mr. E. W. Binney, F.R.S., F.G.S., on the Permian Strata of East Cheshire, was read. The author questioned the correctness of the Government map of the district lying between Macclesfield and Stockport, as far as regards the so-called "red rock fault," by which the coal measures are supposed to be bounded on their dip. According to his observations there is no more evidence of a fault between Macclesfield and Stockport, where the trias and permian beds cover the coal measures, than is to be found on the eastern side of the *Pennine* chain between Sandyacre and Sunderland, where carboniferous strata disappear under permian.—Professor Roscoe, Ph.D., F.R.S., communicated a paper on the Combinations of Phosphate of Lime and Sulphurous Acid, by Dr. B. W. Gerland, of Macclesfield. Phosphate of lime, in whatever state it may be, readily dissolves in an aqueous solution of sulphurous acid. The solution can be obtained of great strength: thus, from freshly precipitated tribasic phosphate of lime a liquor was prepared of 1·3 specific gravity, and from bone ash one of 1·708 specific gravity. The former, on analysis, gave results which agree tolerably with the formula $3CaO$, PO_5, $6 SO_2$. The solution of bone ash in sulphurous acid of 1·1708 specific gravity was also found, on analysis, to contain the amount of phosphoric acid required by that formula. The solution of phosphate of lime in sulphurous acid possesses the taste and smell of the acid, but to a much smaller extent than an aqueous solution of the acid containing the same amount of sulphurous acid. Under the influence of boiling heat the phosphate solution is decomposed slowly, sulphurous acid escapes, and a heavy white crystalline precipitate is formed. Under the microscope this appears to be composed of crystals of the hexagonal system, like those of rock-crystal. Washed and dried over sulphuric acid, it gave, on analysis, results agreeing with the formula $3CaO$, PO_5, SO_2, $2HO$. This sulphited phosphate of lime has no smell or taste, and is distinguished from all sulphites by its stability. Heated in an air bath for three hours to 130° C. it lost 0·64 per cent. of water, but the amount of sulphurous acid remained unchanged; neither had a humid atmosphere the slightest effect upon it. The water is held in intimate combination, and is only expelled at a higher temperature when it is accompanied by fumes of sulphuric and sulphurous acids. The residue contains, besides lime and phosphoric acid, sulphate and sulphide of calcium. The sulphite, which withstands the action of the atmosphere indefinitely, is rapidly oxidised when incorporated with soil. In the soil it acts as a soluble phosphate of lime. It has in fact for several seasons been used as manure, and has given great satisfaction. The new sulphite possesses remarkable antiseptic and disinfecting powers, and on this account will command a general interest. The efficacy of sulphurous acid as a disinfectant is well known; it would be more appreciated if it could be conveniently applied. The aqueous solution is expensive by transport, it is very changeable, and in many cases it is unavailable on account of its pungent smell: whilst for medical purposes it can only be used in exceptional cases, in consequence of its irritating action. The sulphites are still more changeable. Exposed to the air they are acted upon by carbonic acid and by oxygen, and when mixed with decaying organic matter for disinfecting purposes they very often increase the mischief, and sometimes cause an abundant escape of sulphuretted hydrogen. The compound of phosphate of lime with sulphurous acid has none of these disadvantages. Acids, as well as ammonia, are neutralised by it. From a sanitary point of view, ammonia is particularly objectionable; being a product of putridity it helps to accelerate it, and also serves as a vehicle for disseminating other products, which, without it, would not be volatile, or only so to a less degree. The sulphited phosphate, when applied to putrid matter, will probably do its first service by neutralising the ammonia present (including compound ammonias), and also prevent its further formation, as the test paper will show. The smell will soon cease, or at least be greatly diminished and altered, and the mass will be safe for a long time, so that it may be removed or dried without danger or inconvenience. Dr. Gerland remarked that large quantities of putrid matter in open spaces are more completely and speedily disinfected by small portions of the phosphate, than samples in glass bottles. The compound recommends itself as a disinfectant by its physical properties. It is a clean white powder, which stains and soils nothing, dusts off garments or carpets, leaving no mark; it is free from smell and taste, and harmless to animal life. The solution of phosphate of lime in sulphurous acid also possesses disinfecting powers, and acts in many cases even with greater energy than the powder. It might be used with advantage as being applicable to places which could not be reached by the other. The neutrality, regularity of composition, utter harmlessness, and freedom from smell and taste recommend the sulphited phosphate of lime for trial in therapeutics. It would be of interest to investigate it in relation to putrid puerperal fevers, pyæmia, &c.

Microscopical and Natural History Section, November 8.—Joseph Baxendell, F.R.A.S., vice-president of the Section, in the chair.—Mr. W. J. Rideout presented the Section with one of the "Diotamaceen Typenplatte" prepared by J. D. Möller, of Holstein.—Mr. J. B. Dancer sent for the inspection of the members a young cuckoo, which had been caught by a cat in his garden, Old Manor House, Tipping Street, on the 19th August.—The following note was read from Mr. Joseph Sidebotham:—"About fifteen years ago, I had a large cabinet made, of forty-five drawers, to contain shells and carpological specimens, the drawers being made of pencil cedar. Very soon I found that the resinous vapour from the wood became deposited on some of the fruits and shells, making them appear as if they had been dipped in varnish. Chloroform appeared to be the only solvent, and the specimens were obliged to be washed with it. This became so bad that I had the whole of the drawers removed, and replaced with drawers of baywood. Some time afterwards, Mr. Carter advised me to have the cedar drawers sized and papered inside, and a new cabinet made to contain them: accordingly he made me one to contain thirty drawers. These drawers were exposed to the air for twelve months, and very well sized inside, and papered, but the resinous vapour is still deposited on the objects in the drawers as before, and so far is a warning to every one never to use pencil cedar for such a purpose. I should not, however, have thought this matter worthy of mention before the Section, had it not been for the very curious and capricious way in which some objects are coated with this resin, while others are left entirely free, and for which I am totally unable to account. In shells the genera *Conus* and *Oliva* are never touched by it, nor are *Cyprea* or *Mitrea*, whilst *Helix*, *Bulimus*, and *Pecten*, are coated over: this is the case when there are specimens of these and other genera in the same drawer. As this deposit is on the genera I have named, and never on the others, it would seem to indicate that the texture of some shells would attract the vapour and not others. But in the case of bird's eggs, the very strange manner in which some species are picked out as it were and others left, is most remarkable. In the owl's eggs, for substance, the barn owl is always free, while the tawny owl is covered with the varnish, although side by side. The song thrush is never attacked, and the missel thrush always." Trays exhibiting these peculiarities were passed round for inspection.—Mr. Sidebotham also sent a living Death's Head Moth, bred from a pupa, which he had obtained at Lytham, and exhibited that the members might hear its curious cry or squeak when touched.—Mr. H. A. Hurst deposited in the Library a copy of a rare botanical work by a Jesuit priest, the Rev. J. Barrelier, which contained upwards of thirteen hundred carefully engraved plates of plants, which he had collected in France, Spain, and Italy. The work was edited by Antonio de Jussieu, and published in Paris in 1714. Mr. Hurst also exhibited some dried plants, recently collected by Mr. Wanklyn in the Southern States of America. Mr. Coward exhibited species of Podostemaceæ, collected by Gardner, in India and Ceylon. The Podostemaceæ, a little-known order of Tropical Aquatics, closely resemble the Liverworts in habit and general appearance, but possess phanerogamous flowers and dicotyledonous seeds. The order was placed by Von Martius amongst Endogens, in the near neighbourhood of the Naiadaceæ, and by Lindley in his Rutal Alliance of Exogens. Gardner considers it to be nearly allied to the pitcher plants, Nepenthaceæ. The difficulties attending the position of the order were well illustrated in the specimens exhibited, which presented a singular resemblance in foliation to Jungermannia and Riccia, and in the first view of the pedicillated ribbed capsule to the fructification of a moss, but in essential characters the true place appeared to be amongst the aquatic Endogens, with the anomaly of possessing a dicotyledonous seed.

November 30.—The Rev. William Gaskell, M.A., vice-president, in the chair. Mr. J. B. Dancer, F.R.A.S., communicated a paper on the Microscopical Examination of Milk under certain conditions, giving the results of observations made with the view of checking those of M. V. Essling, who states that vegetable organisms, like those found in putrefying substances, make their appearance in milk, before the milk gets sour. On examining a sample of unadulterated milk, Mr. Dancer was unable to detect the appearances described by Essling. The smallest oil globules exhibited as usual great molecular activity, but there was no appearance of dotted matter, or any fungoid growth when the milk was examined by powers varying from 200 to 1,500. A bottle was filled with some of this milk and securely corked; other portions of the milk were placed in open cups: one cup was kept in a cabinet which was closed during the day; the milk of the second cup was placed in a closet, the atmosphere of which was known to be favourable to the growth of fungi, the *Mucor Mucedo* being the most abundant and of the same family as that mentioned as having been found in cream by M. V. Essling. The milk in the bottle and that in the cups was examined daily, precautions being taken to close the bottle speedily after a portion was removed. On the third day the milk in the open cups was sour to the smell, but no change appeared visible under the microscrope; the upper portion of the milk in the bottle had become very rich in oil globules by the formation of cream. On the fourth day the casein had coagulated in the milk in the open cups, and the flaky precipitate was visible under the microscope; the pellicle surrounding the oil globules now appeared to be very easily ruptured, and with the slightest pressure some of the globules could be joined together—sometimes a number of globules which had been ranged in line by a current would coalesce by a slight movement of the fluid, and form an elongated mass. Fifth day, no appreciable alteration. Sixth day, the milk which had been placed in the closet had patches of mould visible on its surface: a microscopical examination of this mould showed it to be the *Mucor Mucedo*, such as had been frequently found on fruit which had been left in this closet. The fungus appeared on the surface only, no trace of it could be found in the milk taken from various depths. The milk in the cup kept in the cabinet exhibited no appearance of the *Mucor Mucedo* or any other vegetable or animal organism; it had become thickened into a pasty mass with an intensely sour odour. These observations were continued for eleven days, and the only difference observable was in the oil globules—they began to lose their spherical form, as if the investing pellicle had been weakened in parts and had become expanded. These experiments were repeated with a second supply of milk, and the results were alike in both cases. The range of temperature during the experiments was from 45° to 63° Fahr. These experiments led Mr. Dancer to believe that vegetable organisms do not as a rule make their appearance in pure unadulterated milk unless it is exposed for some time to atmospheric influences; most probably the spores are supplied by the atmosphere. He, however, considered M. V. Essling's suggestion to bottle the milk very good, and thought that cream pans with covers would be a very great improvement on the open ones as at present employed, at the same time having due regard to the cleanliness of the apartment and vessels in which the milk is kept.

Brighton

Brighton and Sussex Natural History Society, December 9.—The president, Mr. T. H. Hennah, in the chair. A paper was read by Mr. C. P. Smith on the Gemmæ of Mosses. Besides the ordinary mode of generation from a spore, which gives rise to a *prothullus*, from which the perfect plant is developed, mosses have another mode of generation, by means of gemmæ or sprouts, which have been defined as loose granular bodies, capable of becoming plants. As yet, none of the *Pleurocarpi* or side-fruiting mosses have, in Britain, been found producing gemmæ, whose situation on the plant varies in different species. Thus, in *Tortula papillus*, which grows on trees in Sussex and elsewhere, and has a thick spongy nerve, the gemmæ are found in the upper parts of the inside of the leaf—the fruit of this moss is unknown except in Australia; *Didymodon gemmascens*, having the nerve excurrent, has the tip crowded with gemmæ; in *Tetraphis pellucida* they are in pedicellate clusters at the ends of separate stems; in *Bryum atropurpureum* they form tubercles or bulbs in the axils of the leaves. On the leaves of *Orthotrichum Lyellii* grow little strings of cells, which, presenting a confervoid appearance, were named *Conferva castanea*: they have, however, been demonstrated to develop into young plants of mosses. *Oncophorus glaucus* has a great number of cells forming a dense mass at the tip of the leaf: these in the damp season give rise to young plants, so that this moss is common in counties where it never fruits. The subject of the growth of gemmæ has not yet been thoroughly worked out: he purposed investigating the phenomena, when he hoped to have some new facts to lay before the society. The paper was illustrated by drawings and microscopical specimens prepared by Mr. Smith, and exhibited by the following gentlemen, the most striking of which were—by Mr. Hennah, *Mnium cuspidatum*, *M. Hornum*, *Polytrichum commune*, and *Neckera oligocarpa*, showing flowers; Mr. Smith, *Ceratodon purpureum* and *Cinclidium stygium*, showing peristomes, and *Ephemerum serratum*, with prothullus and young buds; Mr. Sewell, section of leaf of *Pottia cavifolia* and *Orthotrichum Lyellii*, with confervoid gemmæ on the leaves, the *Conferva castanea* of the early botanists; Mr. Wonfor, *Aulocomnion androgyum*, *Ullota phyllantha*, and *Tetraphis pellucida*, exhibiting gemmæ.

Paris

Academy of Sciences, December 6.—M. Andral communicated a memoir on the relation of the variations of the temperature of the human body to variations in the quantities of some constituent principles of the blood and urine. In this paper the author discussed the proportion to be observed between the temperature of the body taken under the axilla and the amount of fibrin, albumen, and globules contained in the blood, and that of urea eliminated by the kidneys. He treated of the comparative phenomena presented in various diseases.—MM. Bouillard and Becquerel remarked upon this communication. M. Faye communicated extracts from letters from MM. B. A. Gould and L. Respighi upon the solar atmosphere and prominences, with some remarks upon them by himself. Mr. Gould's letter related to the luminous protuberances observed during the last eclipse. He referred them to the chromosphere, which he regarded as the general atmosphere of the sun, and he accepted the notion that they indicate a predominance of hydrogen in that region, but he inclined to ascribe to this a greater elevation than is generally given to it, especially as the Coast Survey Expedition had obtained photographs which show traces of it at an elevation of 7 minutes. Mr. Gould also remarked upon the evidence furnished by the perihelion distance of the comet of 1843.—M. Respighi's note referred to the relation between the protuberances and solar spots, and he stated that in the neighbourhood of the poles of the sun the protuberances are almost constantly wanting, that they are in close relation with the faculæ and spots, and that the faint shadows which appear upon the photosphere are due to the interposition of the materials of eruptions, which may persist for many days together.—M. C. Marignac presented a paper on the influence of water upon saline double decompositions, and upon the thermic effects which accompany them. He described the mode in which he experimented, and gave the following results:—The dilution of a solution causes a variation of temperature in either direction, which usually diminishes with the degree of dilution, but with sulphuric acid the increase of temperature is augmented by dilution. The mixture of solutions of two salts which do not decompose each other, generally gives rise to an evolution of heat less than that produced by the simple dilution of the solutions. When they can form a double salt, there is usually absorption of heat. The mixture of alkaline sulphates with sulphuric acid causes a considerable absorption of heat. With solutions of the alkaline bisulphates, the addition of water produces a considerable and increasing evolution of heat. The mixture of two saline solutions, or of a salt and an acid capable of decomposition without producing an insoluble compound, gives rise to considerable thermic effects, which, in some cases, at least, are increased by dilution. With mixtures, the result appears to be different according as the dilution is effected before or after the mixture of the solutions.—A note by M. H. Resal, on the relative movements of the water in the curved floats of Poncelet's water-wheel was read; as also a note by M. Bosscha in answer to observations made by M. Regnault upon a previous letter of the author's on the measurement of temperatures.—M. Lecoq de Boisbandeau presented a memoir on some points of spectrum analysis, in which he confirmed Secchi's observations on the spectra of different parts of Geissler's tubes, and communicated his own remarks on the spectra of the aureola of the positive pole, of the blue light of the negative pole, and of the spark itself. He also remarked upon differences caused by alterations in the conditions under which the spark is produced. —M. J. L. Soret communicated a note on the illumination of transparent bodies, in which he maintained, in opposition to M. Lallemand, that this is to be ascribed to suspended particles, especially in water. He described some experiments made by him. M. Chevreul in remarking upon this communication, noticed the decomposition of glass by water even at a temperature of 98° C. (= 208, 4° F.), and referred to the action of other bodies upon glass.—M. J. Maumené presented a reply to M. Dubrunfaut's note on inverted sugar, and M. Dubrunfaut a notice of his investigations of the catalytic phenomena presented by the action of acids upon crystallised sugar by the examination of the rotatory properties of its products.—M. A. Petit communicated a note on the sugar normally contained in wine, in which he stated that he had found in all wines a quantity of sugar varying from 0·50–5 grammes per litre. Sugar also occurs in vinegar.—M. Sanson, in a note on the caballine species of the genus *Equus*, endeavoured to show that our domestic horses belong to eight distinct species.—A memoir on the chemical composition of fossil bones by M. Scheurer-Kestner was presented by M. Milne-Edwards. The author remarked upon the conversion, in fossil bones, of a portion of the ordinary osseine into soluble osseine, and showed by analysis that the per centage of the latter is, *cæteris paribus*, equal in bones of the same date, so that its amount may furnish an almost infallible proof of the contemporaneity or otherwise of bones found together in the same cave or deposit. M. Elie de Beaumont made some remarks on this communication.—Notes were communicated by M. Ruffner on the preservation of meat by sulphurous acid, and on various questions of hygiene, and by M. Coffin on the "metaphysics of the differential calculus;" of these the titles only are given.

DIARY

THURSDAY, December 16.

Royal Society, at 8.30—Researches into the Constitution of the Opium Bases. Part III. On the Action of Hydrochloric Acid on Codeia: A. Matthiessen, F.R.S., and C. Wright.—On the Thermodynamic Theory of Waves of Finite Longitudinal Disturbance: Prof. Rankine, F.R.S.—On Approach caused by Vibration: Prof. Guthrie.

Society of Antiquaries, at 8.30.—On the Descent and Arms of the House of Compton: Mr. Evelyn Philip Shirley, F.S.A.

Linnean Society, at 8.—On a species of *Ipomæa* yielding Tampico Jalap: Daniel Hanbury, F.R.S.

Chemical Society, at 8.

Zoological Society, at 4.

Numismatic Society, at 7.

Philosophical Club, at 6.

London Institution, at 7.30—Architecture: Prof. R. Kerr.

Edinburgh Geological Society, at 8.

FRIDAY, December 17.

Philological Society, at 8.15.

Quekett Microscopical Club, at 8.

MONDAY, December 20.

Medical Society, at 8.

Royal Asiatic Society, at 8.

London Institution, at 4.—Elementary Physics: Prof. Guthrie.

Institute of Actuaries, at 7.

Society of Arts, at 8.—The Spectroscope and its Applications: Mr. J. Norman Lockyer, F.R.S.

TUESDAY, December 21.

Institution of Civil Engineers, at 8.—Anniversary Meeting.

Statistical Society, at 8.

Pathological Society, at 8.

Ethnological Society, at 8.—On an Ancient Calvaria, assigned to Confucius: Prof. Busk, F.R.S.—On the Koords and Armenians: Major Millingen, F.R.G.S.—On the Kitai and Kara-kitai: Dr. Gustav Oppert.

WEDNESDAY, December 22.

Society of Arts, at 1.—On Wines—their Origin, Nature, Analyis, and Uses; with special reference to a new Alcoholic Drink made from Tea: Dr. J. L. W. Thudichum.

Geological Society, at 8.—On the Iron-ores associated with the Basalts of the North-east of Ireland: Mr. Ralph Tate, F.G.S., and Dr. J. S. Holden, F.G.S.—Note on the Skull of the Large Kimmeridge Crocodilian, *Dakosaurus maximus*, Buenstedt, *Steneosaurus*, Geoffr. St. Hilaire: Mr. J. W. Hulke, F.R.S.—Note on a fragment of a Jaw with peculiar Teeth from Kimmeridge Bay: Mr. J. W. Hulke, F.R.S.—Notes on the Structure of *Sigillaria*: Principal Dawson, F.R.S. of Montreal.—Notes on some new Animal Remains from the Carboniferous and Devonian of Canada: Principal Dawson, F.R.S.

THURSDAY, December 23.

Society of Antiquaries, at 8.30.

BOOKS RECEIVED

English.—Home Life of Sir David Brewster: By his daughter, Mrs. Gordon (Edinburgh: Edmonston and Douglas):

Foreign.—Histoire de la Création: par H. Burmeister; traduite de l'allemand: E. Maupas.—Monographie des Ligumineuses Cæsalpinées: H. Baillon.—Die Nordamerikanische Zuckerfabrikation aus Sorgo und Imphy: Dr. Karl Löffler und Peter von Papi-Balogh.—Untersuchungen über Bau und Entwicklung der Arthropoden: Dr. Anton Dohrn.—Ueber die Bauweise des Feldspaths: Dr. Fredrich Scharff.—Japanisches Meeres-Conchylien: Dr. C. E. Lischke.—Die Pflanzenstoffe: Dr. Aug. Husemann und Dr. Theod Husemann—Die Lagerstätten der Nutzbauren Mineralien: Johann Grimm.—Archiv fur Mikroskopische Anatomie: Max Schultze.

CONTENTS

Erratum.—Line 26, col. 2, p. 166, should read as follows: "total number about 200. I have identified at least 60"

Printed by R. CLAY, SONS, & TAYLOR, at 7 and 8, Bread Street Hill, in the City of London, and published by MACMILLAN & Co., 63, Bleecker Street, New York.—THURSDAY, December 16, 1869.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

*"To the solid ground
Of Nature trusts the mind which builds for aye."*—WORDSWORTH

No. 81 THURSDAY, DECEMBER 23, 1869

Registered for Transmission Abroad]

CLERGY MUTUAL ASSURANCE SOCIETY.

ESTABLISHED IN 1829.

OFFICE—No. 2, BROAD SANCTUARY, WESTMINSTER.

TRUSTEES.

The ARCHBISHOP of CANTERBURY.	The BISHOP of WINCHESTER.
The ARCHBISHOP of DUBLIN.	The ARCHDEACON of MAIDSTONE.

CHAIRMAN.
The Venerable the ARCHDEACON of LONDON.

DEPUTY-CHAIRMAN.
The Honourable EDWARD W. DOUGLAS.

ACTUARY.
STEWART HELDER, Esq.

SECRETARY.
The Rev. JOHN HODGSON, M.A.

Total Existing Assurances	£4,473,023	0	0
Total Annual Income	173,545	9	7
Total Invested Capital	1,693,975	1	6

For the year ending 31st May, 1869, 315 proposals, assuring £274,540, and yielding in annual premiums £9,383 16*s*. 6*d*., were completed; and £88,482 13*s*. 1*d*. was (notwithstanding the large reduction made by Bonus in every fifth year from 1831 to 1866, both inclusive) added to the Fund accumulating for the purpose of meeting future claims.

Prospectuses, Accounts of Bonus, &c. &c., to be had at the Office, on application personally, or by letter; also a Pamphlet by the Rev. J. Hodgson, called "Notes on Life Assurance," containing explanations on various interesting points.

Clergymen and their Wives, and the relations of Clergymen and of their Wives, are invited to make Life Assurances in this Society.

OBSERVATIONS IN REFERENCE TO DURATION OF LIFE AMONGST CLERGYMEN.

Established upon investigations made in the case of five thousand Incumbents of livings, from the middle of the last century to the middle of the present.

BY THE REV. JOHN HODGSON, M.A.

Of Trinity College, Cambridge, Secretary of the Clergy Mutual Assurance Society, and formerly Vicar of St. Peter's, in the Isle of Thanet, and Rural Dean of Westbere. To which is added a Supplement, by Samuel Brown, Esq., President of the Institute of Actuaries. Copies may be had of Messrs. C. and E. LAYTON, Fleet-street. Price 2*s*. 6*d*. each.

PELICAN LIFE ASSURANCE COMPANY,

Established in 1797,

70, LOMBARD STREET, CITY, and 57, CHARING CROSS, WESTMINSTER.

Directors.

Henry R. Brand, Esq. M.P.	Kirkman D. Hodgson, Esq.
Octavius E. Coope, Esq.	Henry Lancelot Holland, Esq.
John Coope Davis, Esq.	Sir John Lubbock, Bart. F.R.S.
Henry Farquhar, Esq.	John Stewart Oxley, Esq.
Charles Emanuel Goodhart, Esq.	Benjamin Shaw, Esq.
Jas. A. Gordon, Esq. M.D. F.R.S.	Marmaduke Wyvill, Jun. Esq.

FINANCIAL POSITION.

Total Amount Insured, with Bonus Additions . .		£3,007,431
Liability on the same at 3 per cent. Interest . .		846,712
Accumulated Funds		1,227,253
Annual Revenue from Premiums . . .	£92,787	
" from Interest	57,163	
		149,950

The whole invested in Government, Real, and other first-class Securities, in addition to which the assured have the guarantee of a large and wealthy proprietary.

For Prospectuses and Forms of Proposal apply at the Offices as above, or to the Agents of the Company.

ROBERT TUCKER,
Secretary and Actuary.

NEW ELECTRIC LAMP.—Browning's New Large Automatic Electric Lamp. In this lamp both carbons are moved by the electricity of the battery employed (without the aid of clockwork); the light remains uniform in height, and more steady in action than any of the expensive regulators previously introduced. Price £8 8*s*. Illustrated circular for stamped envelope.

JOHN BROWNING, Optical and Physical Instrument Maker to the Royal Observatory, &c. &c., 111, Minories, E., London. Established 100 years.

SPECTRUM APPARATUS.—John BROWNING has great pleasure in introducing, to the notice of Lecturers and others, an economical set of apparatus for projecting the spectra of metals, or the absorption bands of liquids, on a screen. Illustrated catalogue of Spectroscopes sent for thirteen stamps.

JOHN BROWNING, Optical and Physical Instrument Maker to the Royal Observatory, &c., &c., 111, Minories. Prize Medal, 1862. Established 100 years.

CLARENDON PRESS PUBLICATIONS.

VESUVIUS. By Professor PHILLIPS.

CONTENTS:—Vesuvius at Rest—In Action—In the Nineteenth Century—Periods of Rest and Activity—Characteristic Phenomena—Form and Structure—Minerals—Lava and Ashes, &c. With numerous Illustrations. Crown 8vo. 10*s*. 6*d*.

"Contains much historical and scientific matter reduced to a pleasant and readable form. Of the volume as a whole, we can only speak in terms of the highest praise, and we regard it as a work which deserves a place on the shelves of every student of physical science."—*Examiner.*

"A work of high value both to the student and to the tourist on the shores of the Bay of Naples."—*Pall Mall Gazette.*

CLARENDON PRESS SERIES.

Recently published, in Crown 8vo. price 7*s*. 6*d*.

EXERCISES in PRACTICAL CHEMISTRY: Qualitative Analysis. By A. G. VERNON HARCOURT, F.R.S. Lee's Reader in Chemistry at Christ Church, Oxford, and H. G. MADAN, F.C.S. With numerous Illustrations.

"The plan of the book appears to us to be admirable, and the directions given for performing the various operations involved in the course are wonderfully precise and clear."—*Chemist and Druggist.*

Second Edition with Solutions.

CHEMISTRY FOR STUDENTS. By A. W. WILLIAMSON, Phil. Doc., Professor of Chemistry, University College, London. Extra fcap. 8vo. Cloth. Price 8*s*. 6*d*.

"This volume is really a too rare example of what a good elementary text-book in any science ought to be: the language, brief, simple, exact; the arrangement logical, developing in lucid order principles from facts, and keeping theory always dependent upon observation; a book that keeps the reason of the student active while he strives to master details difficult but never without interest, and that furnishes him with means for practising himself in the right management of each new tool of knowledge that is given to him for his use."—*Examiner.*

Extra fcap. 8vo. cloth, price 7*s*. 6*d*.

AN ELEMENTARY TREATISE ON HEAT, with numerous Woodcuts and Diagrams. By BALFOUR STEWART, LL.D., F.R.S., Director of the Observatory at Kew.

"This compact little treatise is commendable both as an elementary exposition of the chief phenomena of heat and their practical applications, and also as a brief exposition of the philosophical theories which have recently given a new interest to the phenomena. The structure of the work is also excellent."—*Fortnightly Review.*

Demy 8vo. cloth, 856 pp., price 21*s*.

DESCRIPTIVE ASTRONOMY. A Handbook for the General Reader, and also for practical Observatory work. With 224 Illustrations and numerous Tables. By G. F. CHAMBERS, F.R.A.S., Barrister-at-law.

The aim of this work, briefly expressed, is general usefulness, whether in the hands of the student, the general reader, or the professional observer. Great pains have been taken to present the latest information on all branches of the science. The development of Astronomy is now so rapid that unless an author exercises constant vigilance his book must fall behindhand: and it is believed that this volume not only contains the most recent discoveries and deductions, but that in it will also be found information hitherto to be met with only in the publications of learned societies, difficult of access and inconvenient for reference even to the Astronomer, and absolutely out of the reach of the general reader.

Extra fcap. 8vo. price 7*s*. 6*d*.

A SYSTEM OF PHYSICAL EDUCATION. Theoretical and Practical; with numerous Illustrations drawn by A. MACDONALD. By ALEXANDER MACLAREN, The Gymnasium, Oxford.

"It is marked in every line by good sense, and is so clearly written that no one can mistake its rules. We earnestly hope that the book will find not only many readers, but earnest disciples."—*Lancet.*

OXFORD: Printed at the CLARENDON PRESS, and Published by MACMILLAN & CO., LONDON, Publishers to the University.

THURSDAY, DECEMBER 23, 1869.

TOWN SEWAGE

ONE of the most imperative requirements of social life is some means of dealing with those waste products of the human mechanism which are dirt only while they remain out of their proper place, but are capable of becoming a source of serious inconvenience and injury whenever they are allowed to accumulate in the neighbourhood of dwellings, especially in densely populated places. In the case of isolated dwellings, and where the population is scattered, no great difficulty would be experienced in devising simple measures for disposing of this refuse so as to meet all requirements. But wherever the population is concentrated, the difficulty of dealing with house refuse, so as to prevent its becoming a nuisance, and, at the same time, to make it useful, is greatly increased. Partly on this account, and partly because neglected accumulations of house refuse are in the highest degree detrimental to health, the measures adopted in towns for dealing with house refuse have been subjected to the control of the municipal authorities, instead of being left to the option of the individual occupiers of houses; and in modern times it has come to be regarded as one of the first duties of such bodies to provide for the disposal of house refuse so as to preserve the health and life of the populations under their care. This sanitary axiom has indeed been forced into recognition by the ravages of epidemic disease, such as plague, fever, or cholera, and it may now be deemed unquestionable, except where ignorance overcomes intelligence, or where mistaken notions of economy prevail.

On sanitary grounds it has been decided, or, to say the least, very generally admitted, that the most efficient mode of dealing with house refuse is to remove it at once from dwellings, and by means of a copious use of water to sweep it away through underground channels outside of towns. In this way the domestic nuisances that were familiar during the early part of this century have been done away with, the town nuisance that arose from the use of cesspools has been suppressed, and the sanitary state of towns has generally been improved. But the removal of those nuisances has given rise to another one, affecting not only individual dwellings and towns, but the whole country. The continuous discharge of vast quantities of house refuse, distributed through great volumes of water into rivers and streams that are often sources of water-supply for domestic use, has rendered them so foul that this result of sanitary improvements is acknowledged to be a national nuisance, and one of the very highest importance in regard to public health.

Hence has arisen the question, What is to be done with town drainage? And this question still perplexes the Government, municipal authorities, river conservancies, and legal tribunals. In many instances the sanitary works carried out in towns at vast expense have given rise to serious nuisances at places lower down the streams into which the sewage is discharged; in other cases the execution of such works is prevented by prohibition against the discharge of sewage, and in some cases practices in direct opposition to legal enactment are tolerated because no remedy seems applicable.

So much for the difficulties attending the municipal object for getting rid of house refuse. It is now necessary to consider the subject in another light, and inquire what is the "right place" where house refuse is no longer to be regarded as dirt, but as material of value? How is it not only to be got rid of, but also turned to account and made useful? For this purpose it must be remembered that this waste material consists of the portions of our food which have done their work in the process of nutrition, and those portions of it which were not required in that process. In both cases plants are the source from which the constitutent parts of this material have been derived. Those plants again have abstracted them from the land on which they grew, not accidentally, but as an essential condition of their growth. Here, then, in this fact that the constituents of house refuse are essential for the growth of plants, lies the key to the sewage problem, a possibility for the utilisation of town sewage. Thousands of tons of the same substances that are constituents of house refuse are annually imported into this country for use as manure in agriculture—ammonia in the guano from Peru; phosphates, or bones and phosphatic minerals, from all parts of the world; potash from South America and Germany. Thousands of acres of land lie unproductive from want of these substances, and some of their most important sources are only of limited duration. Meanwhile the aggregate intrinsic value of those constituents in the house refuse of this country amounts to several millions annually.

There are, however, serious difficulties to be overcome before the economic object of utilising town sewage as manure in agriculture can be realised so as to fulfil all requirements involved in the municipal object of getting rid of it, and in the still more important sanitary object of preventing it from becoming a source of injury to the public health. These difficulties arise chiefly from the enormous dilution of the sewage, partly by the use of water for removing house refuse, and partly by the admixture of surface water and subsoil drainage. Generally speaking, the constituents of town sewage which have an intrinsic value as manure are so much diluted that a quantity of them which would be worth one shilling in the state of a dry solid like guano or bones, containing only a small proportion of less valuable admixture, is in sewage mixed with from six to ten tons weight of water. Therefore, in order to give land an ordinary dressing of manure in the form of town sewage, it is necessary to apply a very large bulk of that liquid. This can very often be done without any great trouble, especially when the town from which the sewage is discharged lies high, and is surrounded by cultivated land at a lower level; and even when this is not the case, the cost of pumping the sewage to a sufficient height, and the outlay for pumping works, would not generally be a serious obstacle to the application of town sewage as manure. However, the getting rid of sewage involves its continuous daily application to land; and here the municipal object is at variance with the agricultural object, of using the sewage only when it is wanted. Consequently, it would be necessary, in organising a general system of sewage utilisation, to establish a new system of farming; to grow crops specially suited for the frequent application of very dilute liquid manure, and to have the land laid out for cropping in such a manner that there may always be a sufficient area available for disposing of the sewage day by day. Innovations of such a kind are exceedingly difficult to introduce into an art like agriculture, that is practised so much under the influence of tradition and habit; but, in addition to this impediment, there is the more serious one of cost to be incurred in adapting a farm for sewage irrigation. For the farmer, the value of town sewage is to be estimated, not by the intrinsic worth of the substances it contains, but by the amount of those substances which are effective, or at least likely to be effective, in augmenting the produce of his land after due allowance for the influence of season. If sewage containing in each ton twopence-worth of manure be applied to land in such proportion that only one-fourth of the aggregate quantity of manure constituents remain in the land or become effective, then the sewage so applied cannot be worth more than one-halfpenny per ton to the farmer.

It is therefore futile to estimate by calculation, as has often been done, the value of the sewage discharged from a town, and to anticipate, on such a basis, the possibility of making the sewage a source of considerable revenue to the town. Speculations of this kind have naturally eventuated in disappointment and the disgust of all who have been misled by them, without making due allowance for the drawbacks that influence the value of sewage as manure even more than the intrinsic worth of its constituents.

Another circumstance to be taken into account in this respect is the outlay requisite for conveying sewage from the sewer outlets where it is discharged from a town to the land where it can be utilised as manure. Even under the present system of agriculture, farmers would often be glad to have the command of town sewage for application to their land during dry seasons, when the total failure of a crop might be thus obviated. But it rarely happens that this is practicable, owing to the want of any channel of communication between the sewer outlets and the land where it would be useful. Farmers, and even landowners, would rarely be in a position to incur the expense of making such communications, and municipal authorities refuse to do it as being beyond their province. However, if the importance of preventing the pollution of rivers and watercourses were fully appreciated in regard to its influence on public health, there is much reason to believe that the obligation of getting rid of town sewage appertaining to municipal bodies really extends far beyond merely discharging it into a neighbouring stream, and involves a considerable contribution on their part, according to local conditions, towards the outlay necessary for combining the attainment of their special object with that of the farmer by getting rid of the sewage in such a manner that it may be made useful.

It would, at present, be almost impossible to suggest how this object should be realised; for if town sewage is to be applied on the same principle as manure like guano or bones, only in such proportion as to give the requisite dressing of manure constituents per acre of land, the area over which the sewage of a large town would have to be distributed would be enormous, and the attendant expenses of its distribution would be very large. If, on the other hand, the area of land to which the sewage is applied be limited so as to dispose of the largest possible proportion of sewage and keep the cost of arrangements for distribution within the smallest bounds, there would generally be such a disproportion between the actual quantity of manure constituents applied per acre and the possible effect produced on the produce of the land, that the value of the sewage as manure would be greatly diminished; or, in other words, very much of it would be wasted, and still simply got rid of.

Here again sanitary considerations demand attention, and the possible influence which the application of town sewage to land may have on the public health must be taken into account. It is, for instance, indispensable that the use of town sewage in agriculture should be conducted in such a way as to be an effectual remedy for that pollution of rivers which has become a serious national evil. Moreover, if sewage-irrigated farms are to be distributed throughout the country in the neighbourhood of towns, it is still more imperative to know that the adoption of this course will not be productive of injury to the public health. This point should receive the fullest elucidation before any general measures can be taken with the object of utilising town sewage, and the conditions under which that can be effected without risk should be thoroughly investigated.

Such an inquiry would comprise many questions of detail, requiring varied skill, and considerable time as well as labour, for its prosecution; and the British Association Committee that contemplates carrying it out, impressed with the magnitude and importance of the task, has felt the necessity of much larger means for conducting the inquiry than that small sum which the Association were able to grant for the purpose of meeting the expenses of preliminary work. If municipal bodies and landowners respond to the application of the Committee in a manner commensurate with their interest in this subject, and provide adequate funds for thorough investigation, there is reason to expect some considerable step will have been made towards placing the question of sewage disposition and utilisation in a more satisfactory position than it has yet attained.

Besides the main points already mentioned, of getting rid of sewage and turning it to account, there are yet other questions of moment to be considered. The rapid adoption of reformatory methods, in regard to the sanitary state of towns, which has marked the past quarter of a century, has not always been attended with so much improvement as might have been desired. In some instances, serious anomalies have presented themselves in this respect, and there is much reason to believe that circumstances yet remain to be provided for which affect the sanitary state of towns. Mr. Bailey Denton has recently called attention to this matter by pointing out in his letters to the *Times* the fact that, in some instances, the sewerage works of towns have been constructed in such a way as to admit of the soil surrounding the sewer being permeated by sewage, and he has suggested, as a possibility deserving of inquiry, that in this way an effect may be produced similar to the infiltration of house refuse from cesspools into the surrounding soil. If such be the case, it would perhaps account for the fact that in some towns, where every kind of known sanitary precaution has been taken, the reduction of disease and mortality has been but slight. Such an action, though slower than in the case of infiltration from cesspools, would not be less sure in its influence on the sanitary state of a town, and in that way sewered towns may still be exposed to the evils arising from "excrement-sodden soil" which the Medical Officer of the Privy Council has pronounced to be one of the main causes of cholera and fever.

Another point in which there is reason to believe existing sanitary arrangements are defective is the facility of communication between sewers and the dwellings from which they are intended to convey refuse. Some connection of the kind is indispensable for the use of water as a transporting vehicle for the refuse; but little attention has yet been paid to the fact that the very arrangement which facilitates the water-carriage of refuse also favours the regurgitation of foul gases from the sewers into streets and dwellings. The water traps and syphons commonly attached to the connections between houses and sewers are seldom or never sufficient to prevent the passage of gases; and in this way the inhabitants of sewered towns may be exposed to the unwholesome influence of a constant pollution of the atmosphere as pernicious in its action as the use of water polluted with drainage from cesspools, or living over an excrement-sodden soil, has long been recognised to be.

These are some of the chief points which the limits of the present article will admit of being noticed as being comprised in the inquiry to be carried out by the British Association Committee. BENJAMIN H. PAUL

SCIENCE FOR CHILDREN

THE schoolmasters of the present day may be divided into two categories: those who *teach*, and those who *hear lessons;* the latter class, unfortunately for the next generation, being by far the more numerous. The mischief done to the community generally by the shortcomings of inefficient teachers is too well known to every one who has pierced below the surface of the great question of middle-class education. The difficulties, however, that beset a science teacher in his endeavours to force scientific truths into the unwilling and unprepared minds of boys, who have been subjected to the sway of these same lesson-hearers, can only be realised by those who have gone through the task. The case of a senior science class, which has been under my charge for some months past, will illustrate my meaning most fully. It consists of about a dozen boys, whose ages range between fourteen and seventeen years, and they receive twice a week an hour's instruction on chemistry and physics. The class may be divided into two distinct portions by a perfectly sharp line. Four of the boys have had the advantage of six or seven years' training under the principal of the school, who is not only a ripe scholar, but also an efficient teacher—a very rare collocation in these days. The rest have simply learnt lessons all their lives. The four boys who have been *taught* are as mentally distinct from the others, as if they were different species of the same genus. The first four are bright, attentive, wide-awake—I know of no other term to express exactly what I mean—logical, and clear-headed; they can fairly follow a chain of scientific reasoning, and reproduce it afterwards link by link; they have a certain power of induction and deduction, although of course, being new to science, this power is necessarily only just awakened; they can connect and correlate facts and ideas, they can enumerate a series of phenomena in logical sequence; in a word, although their industry and application are far from colossal, the task of teaching them the truths of natural science is a comparatively easy one. The other boys, as I have said before, almost form a distinct mental species. They cannot understand the possibility of learning anything without the aid of a book, and the idea of finding out anything for themselves has never entered their heads. Still they are far from stupid boys, being all possessed of good average brains; yet their faculties have not merely been allowed to remain undeveloped, but they have been utterly entangled, stunted, and stultified by what Dr. Frankland would call their "previous school contamination." These boys, it must be understood, are the sons of parents belonging to the upper stratum of the middle class, and have mostly been to schools conducted by university men with honourable initials appended to their names—men, in fact, who are scholars but emphatically no teachers. Their great fault is a total want of mental method, without which the greatest brain is as nought. They are at home in Virgil and Horace, some of them are fair Greek scholars; they have "been through" Euclid, and can work moderately difficult algebraical problems in a certain mechanical fashion; they are well acquainted with the leading facts of English history, and know the exact position and population of Adrianople; but as far as real mental power goes, any poor boy, who has been in a National school for three years, would beat them hollow.

These facts surely point out the absolute necessity of beginning scientific training at a very early age; and I fancy this necessity has not been sufficiently dwelt upon in the numberless essays, letters, lectures, and evidence on the subject of scientific education with which we have been deluged during the past decade. There seems to have been a notion abroad, that scientific teaching should not be begun before the age of 12 or 14; but why, I would ask, should boys' minds be allowed to remain fallow during all these years? The minds of boys of 7 and 8 should surely be as carefully developed as those of their seniors, and there is certainly no means of pure mental culture so successful as scientific teaching. A boy of this age should not be taught science so much for the sake of acquiring a certain number of facts, as of developing his powers of observation and reasoning, and giving a proper tone to his mental faculties. A boy of 8 or 9 takes a morning canter of three or four miles on his pony, not for the purpose of getting over some 7,000 yards of ground, but to strengthen his muscles and improve his carriage: his science lesson should be an intellectual canter, taken with the view to strengthening and improving his mental muscles and carriage.

In National and British Schools, and in some few middle-class schools conducted on rational principles, this great want is supplied by what are known as "Object Lessons." A natural object, such as a piece of lead or sugar, is placed before the class, and its physical properties are described by the pupils with the aid of questions from the teacher. Its origin and manufacture are also given in the case of the older children, and the whole is noted down on the black-board in as condensed a manner as possible; the lesson being reproduced in a miniature form either *vivâ voce* or in writing. These lessons are most excellent in their way; but as generally taught, they are too desultory and unsystematic to effect fully their intended purpose. The principal manuals on the subject show a want of arrangement and system, that greatly detracts from their value. One day the children are supposed to learn a lesson on a piece of iron: the next on a flower, the third on a shell, and so on. Too much stress is laid upon cultivating the powers of observation, and too little on connecting the facts observed, and drawing conclusions from them. The lessons, too, are very frequently unconnected with each other, and the facts taught lean almost too much towards the practical and economic side of knowledge, and too little to that of systematic science. Great scientific ignorance is displayed in many cases: for instance, one book informs us that plumbago is an ore of iron; that iron is generally found as an oxide in combination with *sulphuric* and carbonic acid; that fluor spar is composed of fluoric acid and lime; and that lime unites with various proportions of carbonic acid. These mistakes are the result of imperfect scientific knowledge, and may be passed over for the sake of the valuable instruction given to teachers, which cannot fail to produce most excellent results, if applied to systematic scientific teaching.

It may be urged that children of 8 or 9 are too young for systematic science teaching, but facts prove the contrary. An ordinarily intelligent boy or girl of this age is perfectly capable of understanding the broad differences between the animal, vegetable, and mineral kingdoms; that there are more gases than one in the world; that some of them are colourless, while others are brown or green; that some burn and others do not; that some plants grow from the inside, while others grow from the outside; that some animals have jointed backbones, that others have their bones outside their bodies, while others have none at all. Facts such as these are perfectly comprehensible to children even younger than those I have named. During the first two years of a child's school life, after he has learned to read and write, he should be carried through the whole range of physical science in a systematic manner. The fundamental truths of chemistry and physics should be first taught him: all theoretical considerations being left aside. As few definitions as possible should be given, the whole task of the teacher at the commencement being to cultivate the child's powers of observation to the utmost. Gradually the powers of induction and deduction may be developed, facts and phenomena should be compared, and conclusions drawn from them. Order in thought and description should be specially insisted upon, and occasional retracings of the ground already gone over should take place. The objects of this preliminary science teaching should be twofold: first and foremost, to train the mind and form the judgment; and secondly, to give the child a general idea of the object and scope of the natural sciences. At the age mentioned, the faculties are all fresh, and in full process of development; and such is the desire to exercise them in intelligent children, that their thoughts often run wild. There is nothing a child likes so much as investigation, or "finding out all about things," as he himself would phrase it. The boy in the nursery rhyme who cut the bellows open to see where the wind came from, is a type of his class. Unfortunately at the present time, scientific teachers for children are extremely rare, but let the want once arise, and the demand will soon be met. We have plenty of scientific teachers and lecturers for boys and men, but the child has hitherto been left out of consideration. Teachers, in the true sense of the word, are every day on the increase, and even the old-fashioned schoolmasters are beginning to see very plainly that they must alter their system of instruction, and yield to the pressure of the times. But it is not only upon these that I would urge the necessity of beginning science teaching at the earliest possible period, but also upon those who have already adopted science as part of the ordinary school curriculum for the older boys.

CHARLES W. QUIN

THE GOLD FIELDS OF VICTORIA

The Gold Fields and Mineral Districts of Victoria. By R. B. Smyth. (Melbourne: J. Ferres. London: Trübner and Co.)

I.

TWENTY short years ago, the territory of Southern Australia comprised within the colony of Victoria offered comparatively little attraction to the emigrant. Its population had increased but slowly during the half century which had passed away since the discovery of Port Phillip Bay. Graziers, shepherds, and farmers were its chief occupants, and by them the value of its soil was estimated very much according to the number of cattle or of sheep which each acre could maintain. But to-day everything is changed. The land is dotted with hamlets, villages, and towns, and is intersected with roads and railways. The population has increased from 77,000 in 1851, to 660,000 in 1867. In the former year only 57,000 acres were under cultivation, in the latter the area had risen to 631,000. This growth in the population has been accompanied by a corresponding increase in the value of the imports and exports, which are now ten times what they were; while the value of rateable property in town and country districts is estimated at about £42,000,000.

This marvellously rapid rise of the colony is mainly to be ascribed to the discovery of gold there in 1851. Never had the prospects of the colony been gloomier than just before that discovery was made. The able-bodied part of the population was moving off to the gold-fields of New South Wales, glowing accounts of which appeared from week to week in the newspapers. Every kind of property was sinking in value. At last, after small finds of gold had been reported from different parts of Victoria, a public meeting of the citizens of Melbourne was convened, for the purpose of raising funds towards offering a reward to any one who should discover a workable gold mine within twenty miles of that town. The attention of the colonists was now thoroughly roused, and in the course of a few weeks reports came from many of the surrounding districts that gold existed in large quantities. From that time the tide of emigration from the colony was arrested, and the population began to increase with that wonderful rapidity just alluded to.

From the very beginning of the mining operations they were regulated and inspected by the Colonial Government. A mining department was instituted, with a responsible minister at its head. Mining registrars and surveyors, wardens of mining districts, and other officials were appointed with the view of aiding and regulating the labours of the miners, and collecting every variety of information for the use of the Government. More than this, a geological survey was established, under the direction of one of the ablest of the staff of the Geological Survey of the United Kingdom, Mr. Selwyn; and funds were furnished for the production of maps, sections, and other publications necessary for elucidating the geological structure of the colony. That survey has done excellent work, the real value of which may possibly not be understood in the colony for some years to come. We cannot but regret, therefore, that in a spirit of parsimony the colonial Parliament has recently abolished the survey, and deprived the colony of the great advantage of obtaining accurate information as to the mineral tracts which remain yet to be explored. Nevertheless, for what has already been done to develop her mineral resources, and to gather accurate information regarding the structure of the rocks, and the distribution of gold, the colony may be very heartily congratulated.

The handsome volume, whose title heads this article, tells the story of the rapid rise of Victoria. It is a large thick octavo, beautifully printed, and embellished with many woodcuts, sections, and plans of singular excellence, the whole having been prepared and executed in Melbourne. Mr. Brough Smyth, Secretary for Mines to the colony, seeing the want of any trustworthy account of the gold-fields of that region, and having himself peculiar advantages for the task, proposed to himself to compile a narrative of all that was known regarding the mineral districts, the different modes in which the gold occurs, and the various methods in use for obtaining it. He has carried out the project with most commendable patience, and has produced a volume about the Victorian mines which is itself quite a mine of information both to the practical digger and to the geologist.

After a brief introduction, in which the author traces the successive steps which led to the commencement and prosecution of his work, he sketches the general topographical and geological features of the mineral districts. He then briefly describes the circumstances attendant on the first discovery and earliest mining of gold in Victoria, and passes on to treat of the different modes in which the gold occurs. The older or basement rocks are of palæozoic age. They are plicated and denuded very much like our own Silurian strata in Wales, Cumberland, and Scotland. They are, as a whole, but little altered, consisting in large measure of sandstones, mudstones, and shales, which now and then pass into harder and somewhat schistose varieties. Across these strata run thousands of quartz veins, which vary in thickness from one-sixteenth of an inch to 100 and 150ft. Although gold has been found in small quantity disseminated between the planes of bedding of the sandstones, it is in these quartz veins that it chiefly occurs *in situ*. It takes many forms—fine flakes or grains floating, as it were, in the quartz, ramifying threads or moss-like aggregations, spangles, thin plates like gold-leaf, well defined crystals, irregular strings, rough lumps, and large nuggets. How the gold got into the veins is a question on which Mr. Brough Smyth brings forward much argumentation from different writers holding discordant views, but which he does not himself attempt to solve.

Overlying the palæozoic rocks with their quartz veins are "drifts" and alluvial accumulations of different ages. These are very generally auriferous, the gold occurring in detached fragments, varying in shape and size from mere dust up to masses like the "welcome stranger nugget," which weighed upwards of 2280 ounces. There are features of special geological interest in these alluvia, which will be noticed in a second article. The very soil is sometimes full of gold, particularly where it overlies, or slopes from, a quartz-reef. In one place a patch of such soil, about twelve feet square and one foot deep, yielded 30 ounces of gold, even with such rude processes of extraction as were in use in the early days of the gold-fields.

Mr. Smyth arranges the different methods of working gold as follows:—

"(1) *Surfacing*—the washing of the thin covering of earth resting on the tops and sides of the hills in the close neighbourhood of auriferous quartz veins.

(2) *Shallow-sinking*—the obtaining *washdirt* from off the surface of the old claystones, sandstones, and slates, by sinking pits, or making excavations in the valleys and creeks.

(3) *Sluicing and hydraulic mining*—the washing of the auriferous earths, by streams of water, in the gulleys and valleys where recent deposits of auriferous gravels and clays occur.

(4) *Deep sinking*—the obtaining auriferous earths by penetrating the deeper tertiaries.

(5) *Tunnelling*—the obtaining auriferous earths and veinstones by adits.

(6) *Quartz-mining*—the obtaining gold from the mineral veins intersecting the older sedimentary rocks."

The author gives copious details of these different processes as carried on in the various claims and fields. Much of the information so given has necessarily but a local interest, yet its compilation into the present accessible form cannot but prove of much service to those practically engaged in gold-mining in the colony. Some idea of the richness of the Victorian gold-fields may be obtained from the fact that from the first discovery of the precious metal in 1851, up to the end of last year, there had been obtained 36,835,691¾ ounces, estimated as equal to £147,342,767. In the year 1854, just three years after the first discovery of gold, and when the gold-fever was at its height, the number of miners was 65,763. Since that time the numbers have slowly diminished, and in September, 1868, they stood at 63,482. There has been a still more marked diminution in the amount of gold reported. In 1856, the quantity sent out of the colony reached to 2,985,991 ounces, while last year it was only 1,657,498 ounces.

Besides gold, Victoria furnishes other valuable mineral resources. Ores of silver, tin, copper, antimony, zinc, lead, cobalt, bismuth, manganese, and iron occur, some of them in great abundance. Coal, lignite, and bituminous shales are likewise met with; while among the mineral produce of the colony are likewise enumerated the sapphire and the diamond.

The author's official position as Secretary for Mines afforded him excellent opportunities for collecting information regarding the mines in every part of the colony. But such official experience does not necessarily bring with it any practical knowledge of mining, still less any acquaintance with the geological facts which guide mining operations. Mr. Smyth modestly says of himself: "I wish it to be distinctly understood that I am merely a compiler." But his book abundantly proves that he has a thorough knowledge of what practical mining is, and that he is no mere tyro in geology. A tolerably good test of the accuracy of a man's geological knowledge is often furnished by the way in which he draws a section. He is compelled to put down definitely the notion which he has formed of the structure of a district, or of the relations of certain rocks to each other, and the manner in which he does this may be usually regarded as an indication of the extent of his acquaintance, not merely with the locality in question, but with the fundamental laws of geological structure. At the same time, too, he unconsciously betrays whether or not Nature has gifted him with any trace of the artistic faculty. Now Mr. Smyth's sections are singularly excellent. He procured them from miners, mining companies, geologists, and private friends, and no doubt, in many cases, from his own observations. Everybody who has ever tried to collect sections in this way knows that they come in every conceivable style and scale, usually grossly exaggerated either in length or height. Such were doubtless the sections which arrived at the Victorian Office of Mines. But Mr. Smyth has recast them after his own pattern, and they now appear in a uniform kind of drawing, which reminds one of the artistic finish introduced many years ago into geological section-drawing by the late Sir Henry De la Beche.

It is hardly possible to over-estimate the advantages which must accrue to mining interests in the colony when the Government department of Mines possesses a secretary who is evidently most thoroughly in love with his work, and who is endowed with so much sound scientific knowledge and experience. This book is an eminently practical one. Yet it offers every now and then glimpses into geological questions of the highest interest. To some of these reference will be made in a subsequent article.

ARCH. GEIKIE

OUR BOOK SHELF

Terrestrial Physics.—*Probleme der vergleichenden Erdkunde.* By Oscar Peschel. (Leipzig, 1870.)

THE fundamental thesis of the author, involving his conception of the true province of the science of comparative terrestrial physics, appears to be this:—If a series of maps of the globe, or any part of it, drawn at different times during several centuries, be compared, there becomes obvious a radical want of truthfulness in the elder representations; such coast-lines, such mountain-chains, such river-courses are utterly impossible. On the other hand, a modern map convinces us at once of its internal truth. This truth must be founded on some general laws, which must be discoverable by studying the resemblances in the external features of countries; and finally a series of such resemblances distributed over different localities must lead to the discovery of the conditions of their origin.

One example, taken at random, will be sufficient to indicate the author's method of procedure. A comparative study of the localities, where fiords occur, shows—(1) that they are mostly to be found on west coasts, and appear generally associated, rarely single; (2) that they are limited to high latitudes, and excluded from the region confined on both sides of the equator by the isothermal line of 10° C.; (3) that they are all within the region of rainfall during the whole of the year. Hence the general law is deduced, that fiords owe their origin principally to certain climatic conditions, viz. a low temperature, a maximum amount of aqueous deposition, and protection from the drying influence of easterly winds.

Now, we can well admit the possibility, or even probability, that continued actual observations may lead to similar conclusions; but in the mean time we are at a loss to understand how rain or isothermal charts, representing most recent conditions, can be applied to explain phenomena which the author himself thinks must have happened so long ago, that the time would have to be reckoned by hundreds of thousands of years.

M. Peschel, as it appears from his own admissions, has never left his study to observe the phenomena on which he reasons. He has collected, extracted, compiled, compared, and—generalised. This is not the legitimate approach to Nature's secrets, and consequently the author's work, although written in a masterly style, leaves us comparatively in the dark. It is the ingenious pleading of a lawyer for the cause he has undertaken, rather than the transparent and triumphant language with which the genuine student of Nature proclaims his discovery to the world.

Cinchona Plantations in Java. *Die Chinacultur auf Java.* Von J. W. Van Gorkom, ans dems Holländischen übertragen von C. Hasskarl. (Leipzig, 1869.)

THE efforts of the English Government to establish the quinine-producing plants of South America in our Indian possessions have excited very general interest. Other European Governments are, however, not less alive than our own to the danger of depending any longer solely upon the chance products of the forests of South America for supplies of the most indispensable of medicines. Our neighbours, the Dutch, have for more than twelve years devoted much attention to the regular cultivation of cinchona trees in Java, and although the results obtained hitherto are not so favourable as we should have hoped, there is good reason to believe that the experience now gained will lead to great success in the future. The scale on which the Dutch experiments are being made will be best indicated by the fact that on the 31st March last there were in Java in nurseries and regular plantations nearly a million cinchona plants under cultivation. Besides these, more than 900,000 have been planted in the jungles, but have, unfortunately, owing to a variety of causes, already mostly disappeared. In the present pamphlet M. von Gorkom gives the experience of the Dutch cultivators, as well as a general review of the literature of the subject. Appended to the pamphlet are tables showing the present state of cinchona-culture in Java, the rate of growths of the plants, and the results of chemical analyses of the various species cultivated. Monsieur van Gorkom has had the advantage of having his work rendered into the more generally accessible German language, by a gentleman who has himself taken so distinguished a part in cinchona-culture as to induce a jury of the French International Exhibition of 1867 to confer a gold medal upon him, while assigning to Markham, McIvor, and others silver medals only.

Transactions of the Bremen Scientific Association.—*Abhandlungen des naturwissenschaftlichen Verens zu Bremen.* Vol. 2. part i. (Bremen, 1869.)

AN article by Dr. Foske on the late Professor Trevirarus points out that in some of his works the fundamental ideas of Darwinianism were clearly expressed, long before the theory was explicitly propounded by Mr. Darwin.

We would direct the attention of biologists to a paper in the same volume, by M. Luerssen, "On the influence of red and blue light on the plasma-stream in the hairs of *Urtica* and *Tradescantia virginica*." It appears that the action of red light is to disturb the molecular structure of the protoplasm, and finally to destroy it entirely, while blue and white light act similarly; the blue, however, with somewhat less energy.

B. L.

SENSATION AND PERCEPTION.—I.

VERY different meanings have been attached to the words sensation and perception by different writers; and this diversity of meaning is to be met with in physiological as well as in more strictly philosophical works. Yet it is most important that we should come to a definite understanding upon the subject, in order to know whether certain physiologists have been warranted in assigning sensation and perception to different parts of the brain, as functions of separate portions of this principal organ of mind.

The distinct issue raised is, Are physiologists justified in assuming that the so-called sensory ganglia, at the base of the brain, are the centres in which mere unconscious nerve impressions are converted into conscious sensations? are these ganglia, in fact, in any sense, seats of Consciousness?

Almost everyone understands that both sensation and perception, however they may be supposed to differ from one another, are nevertheless conscious states, or modes of consciousness in the special and ordinary acceptation of the term. But there is one distinguished writer, at least, who has most strenuously objected to this limitation, in the case of the word sensation. Mr. G. H. Lewes maintains* that what most other people term mere impressions or unconscious nerve actions, should really be regarded as sensations, and should be entitled also to the attribute of consciousness—not in its more special acceptation, but in accordance with the very general meaning which he attaches to this word. For the sensations and perceptions of other writers—those impressions to which our attention is given—he reserves the single term perception, apparently because he considers there is no fundamental distinction between them. With this latter part of his doctrine, as will be seen, we are disposed thoroughly to agree, though we cannot assent to the propriety of so far revolutionising the meanings of the words sensation and consciousness. The fundamental position which Mr. Lewes assumes, and upon the strength of which he considers it desirable to make such an innovation in the meanings of thoroughly accepted terms is:—"that sensibility is the *property inherent in ganglionic tissue*—the one peculiar 'force' belonging to all nerve centres, as neurility belongs to all nerves."† Now Mr. Lewes himself points out, that the only means of upsetting his argument (which must be otherwise logically irrefutable) is to deny that sensibility is a *property* of ganglionic tissue, and to look upon it as a *function* rather of certain nerve centres. And this really seems to us to be the conclusion most strongly supported by obtainable evidence. Instead of believing sensibility to be the property inherent in ganglionic tissue, should we not rather assign to this some more general characteristic, such as molecular instability, conferring upon it a property of mere *impressibility*—of which sensibility and consciousness are the most specialised modes, dependent upon the organisation and molecular instability of certain nerve centres of the cerebral hemispheres? Mr. Herbert Spencer‡ calls a ganglion cell a *libero-motor* element; because in the most general conception of its property it seems to be a portion of extremely unstable matter, in which the molecular movements imparted to it by the afferent nerve-fibre undergo a prodigious multiplication before producing their ulterior effects.

Just as we meet with this notable exception to the generally received meaning of the word sensation, so also has the word perception been endowed with an altogether special meaning, by that school of philosophers known as Natural Realists: some of them have removed it also from the sphere of consciousness as ordinarily understood. Space will not permit of my showing how they differ amongst themselves in minor shades of meaning:

* "Physiology of Common Life." vol. ii. 1859.
† Loc. cit. p. 20.
‡ System of Philosophy, No. 20, 1868.

I will only now quote the views of Dugald Stewart. He says:*—"In order to form an accurate notion of the means by which we acquire our knowledge of things external, it is necessary to attend to the distinct meanings of the words *sensation* and *perception.* The former expresses merely that *change in the state of the mind* which is produced by an impression upon an organ of sense (of which change we can conceive the mind to be conscious without any knowledge of external objects); the latter expresses the *knowledge* we obtain by means of our sensations of the qualities of matter." This is an explanation of perception which to most physiologists would appear absolutely meaningless. It seems itself utterly incomprehensible. Stewart conceived perception to be a distinct mental act by which we obtain a "knowledge" of the properties of matter as existing, and in themselves. But, strange to say, this "knowledge" we "obtain by means of our sensations;" even though by the word *sensation* Stewart understood "merely that change in the state of the mind which is produced by an impression upon an organ of sense." How, through such changes in the state of the mind, we are to arrive at an immediate knowledge of the *things* without which, *ex hypothesi*, the changes are not produced, we are at a loss to understand; and neither do we see how it can be reconciled with Stewart's own theories, seeing that, according to him, consciousness "denotes the immediate knowledge which the mind has of its sensations and thoughts, and, in general, of all its present operations." On the one hand, "knowledge" is made to transcend the sphere of consciousness; whilst on the other, it is said that "of all the present operations of the mind, consciousness is an inseparable concomitant."

With these exceptions, the different acceptations of the words sensation and perception are less divergent, inasmuch as nearly all other writers suppose consciousness, in the ordinary meaning of the word, to be an attribute of both states. And if they are both modes of consciousness, then the only further question to be considered is, whether there is any fundamental difference between them, such as would warrant physiologists in assuming the existence of an organic centre for the realisation of sensations, altogether distinct and apart from that whose functional activity gives rise to perceptions; or whether the two words are applicable only to the extremes of a series between whose terms there are the most innumerable and insensible gradations? If the latter view be the correct one, if the difference is one of degree rather than of kind, then we should be much more consistent in regarding sensations and perceptions as arising from the activity of one and the same organ; and from a consideration of this question we may, therefore, derive some help towards the correct interpretation of the results of operations on the brains of certain lower animals, which have hitherto given rise to much discussion amongst physiologists.

Professor Bain has well shown, in his "Emotions and Will," how sensation in its most strict acceptation does insensibly merge into that which is more usually spoken of as perception. He shows that the more "sensation involves cognitive or intellectual processes, the more liable is it to fall under the title of perception." "Some sensations," he says, "are mere pleasures and pains, and little else; such are the feelings of organic life, and the sweet and bitter tastes and odours. Others stretch away into the region of pure intellect, and are nothing as respects enjoyment or suffering; as, for example, a great number of those of the three higher senses." But it seems to us that Mr. Bain stops short of the truth when he says,† "the lowest or most restricted form of sensation does not contain an element of knowledge." It does not contain knowledge, it is true, in its highest sense, involving affirmation and belief, but as a state of consciousness it is

* Collected works of Dugald Stewart, edited by Hamilton, vol. ii. p. 14.
† Loc. cit. p. 586 (Second Edition).

inseparable from knowledge in its essence, which implies *discrimination of difference or agreement*. We, in common with others, would rather believe that no sensation, not even the simplest, can exist without the elements of cognition being at the same time present in consciousness.

The word perception has, undoubtedly, been used for the most part to signify something which may be termed an intellectualised sensation, and in the purest form of it the amount of mere feeling is reduced to a minimum, whilst the amount of intellectual action involved has undergone a corresponding increase. A perception is a fully elaborated sensation, from which we derive our notion of the nature of an external object—such object being recognised immediately and intuitively, not so much by the mere light of the single present impression, as by the blending of this with revived memories of all other impressions which have, at various times, been related to the one now present. Thus we get a comprehensive notion of the nature of the external object, though a notion which must, to a certain extent, vary with the individual according to the nature of his previous experience. A savage who had never seen gunpowder before, would have a very different notion called up by the sight of it, from that with which a European would be inspired who well knew its composition and properties. To the one it would be a simple black powder, and by him it would be perceived more or less simply as belonging to this category; whilst the other's notion of the same substance would be more complex, containing ideas as to the ingredients of which it is composed, and as to the effects which it is capable of producing by explosion in various ways. But between such states of knowledge, and others which might be regarded as the simplest specimens of mere feelings or sensations, there is not a difference in kind, only one of degree. Any sensation, however simple, can only be recognised as such—can only be revealed in consciousness—inasmuch as it presents a certain quality or qualities, by which it can be differentiated from or classed with previous states of feeling. Therefore even the most simple sensation does necessitate the existence of intellectual activity, since discrimination is the most fundamental mode of intellect. And, in those more complex sensations, generally named perceptions, the only difference, as previously indicated, is that the feeling, as mere feeling, is reduced to its lowest ebb, whilst the amount of intellectual activity, combined in the form of discrimination and memory, has proportionately increased. For by virtue of that association always occurring during the education of the individual between various related sensations, organic and organised relations have been established in the brain, so that a present sense impression rouses simultaneously memories of other past impressions derived from any given object, either by the same or through different avenues of sense; and this blending either actually or potentially of all our past knowledge concerning the same or similar objects with the new impression, goes to constitute our then present perception. "Thus," as we have said elsewhere,* "I see an orange at a distance: this, as an object of visual sense, is simply a rounded yellow area; but past experience has led me to know what are the tactual and muscular sensations usually associated with the sight impressions—how it is really a spherical body with a somewhat rough surface. Then I have learned also that these impressions are usually associated with a certain odour, with a certain taste, a degree of succulence, and certain internal optical characters, including a divisibility into segments, and the possible presence of seeds within. A combination of any of these, or of a host of other revivable impressions, may go to constitute my perception of an orange, and may flash into consciousness more or less simultaneously on the presentation of the object to the visual sense." But as we have previously said, between this comparatively complex resultant, and what would be called a simple sensation, some mere odour or taste, there are other sensations of all intermediate degrees of complexity; and even such simple forms of sensation could not be realised in consciousness without our *knowing* them as sensations possessing such and such characters: to be *known* at all, they must be known qualitatively, and to recognise their qualities is to know them in relation to certain other past impressions which we may have experienced; and thus, in fact, we may look upon it as almost certain, that even the simplest conscious impression can only be known or realised in consciousness so long as intellectual action of some kind is brought to bear upon its recognition.

* "On the Muscular Sense, and on the Physiology of Thinking." (Brit. Med. Journal, May 1869.)

Hence it may be legitimately maintained, that there is the strongest *à priori* objection to the view which has been so generally held amongst physiologists, that there is an inherent difference between a sensation and a perception, and that there are distinct nerve-centres, by the activity of which such states or acts respectively are called into being. And whilst psychological evidence is thus strongly in favour of the supposition that all sensations, whether simple or complex, do reveal themselves in one organ only, we think we shall also be able to show that physiological evidence is, moreover, quite in harmony with the opinion that the cerebral hemispheres themselves are the sole seats of consciousness, whether for simple sensations or for complex sensations; and that there is no lower organ for "mere sensations" only, as they have been termed—no *sensorium commune* as ordinarily understood, in which impressions reveal themselves in consciousness before impinging upon the cortical grey substance of the cerebral hemispheres.

H. CHARLTON BASTIAN

MISTLETOE

WHEN the leaves are rotting on the ground, and the fruit has been converted into cider, the orchards of Herefordshire and Worcestershire still retain something of their verdant hue, and are green with what seems at first to be untimely foliage. But mistletoe cannot be unseasonable at Christmas, and there are those who would be glad to have it in season "all the year round." The supply from the West Midland Counties is practically inexhaustible, for it has been calculated that from 30 to 90 per cent. of the apple-trees are infested by this parasite, two or three boughs of which may sometimes be seen dependent from some old cankered limb. Its presence is at once the cause and the sign of incipient decay. A struggle for life between the tree and its enemy has begun, and, if the pruning-knife or the demands of Christmas do not interfere, the mistletoe will slowly and surely exhaust the branch upon which it grows, penetrating further and further into the wood as the supply of sap recedes, and ever sending forth fresh roots in place of those which were overpowered at first. The severity of the struggle between these seemingly unequal foes may be sometimes seen in the strange fantastic contortions into which the branches twist themselves, and sometimes in the withered aspect which the whole tree wears when, as Shakespeare says, it stands

> Forlorn and lean,
> O'ercome with moss and baleful mistletoe.

The entire existence of this parasite is full of interest, even though the mystery of its birth has been removed. Modern research confirms the accuracy of the old distich which expresses thus its origin:—

> The thrush, when he pollutes the bough,
> Sows for himself the seeds of woe;

and perhaps the increase of mistletoe may be partly attributable to the disuse of its product (bird-lime), and the greater immunity which thrushes in consequence enjoy. But those who desire to do so may easily propagate mistletoe without their intervention. All that is necessary for success is to introduce very carefully a few seeds into a shallow notch made in the bark of an apple-tree, and bind it round delicately with bass or damp moss. The apple-tree is the surest stock, for, though it is found elsewhere, yet there is a certain constancy in the apparent caprice shown by the mistletoe in the selection of its victims. It occurs frequently on the poplar, hawthorn, willow, and lime; never on the beech, holly, cherry, and walnut; rarely on the chestnut and pear, and only in some few known instances upon the oak. Probably the rarity of its occurrence on the oak contributed to the reverence with which, under those circumstances, it was regarded by our British ancestors. To them a mistletoe-oak was a tree beloved of heaven—a symbol of life and death—a promise of renewal of strength to the leafless monarch of the glade. When the New Year's festival came round, the Arch-Druid, clothed in white, mounted the tree, and cut the mistletoe with a golden sickle. As it fell into the white cloth held to receive it, two white bulls also fell to the ground as sacrificial victims; and the prayer went forth from the Druid's lips that God would prosper his gift, and make it a charm potent against poison, and a certain cure for sterility.

It is curious to notice how this traditional connection between the mistletoe and New Year's Day, and a belief in its virtues, have survived among the natives of the Western Marches. In Herefordshire, at any rate, no mistletoe enters into the Christmas decorations of house and church; but on New Year's Eve, many of the old farmers and cottagers still go forth to cut their bough, and hang it up with all solemnity as the clock strikes twelve. Nor are the medical properties of the mistletoe forgotten by them. Before turnips were extensively cultivated, old Tusser's precept was regularly followed:—

> If snowe doe continue, sheepe hardly that fare
> Crave mistle and ivie for them for to spare.

And even now faith in the virtues of the plant (which is in fact a gentle tonic) may here and there be found. "What is mistletoe good for?" asked Dr. Bull of a Herefordshire rustic. "That do depend on what tree it comes from," was the reply. "It be a very fine thing for fits. My father had the 'leptic fits for many years, but nothing never did him no good like mistletoe from the haw, mixed with wood-laurel, and he took nothing else. They do tell me that mistletoe from the maiden ash be a fine thing for convulsives. I know when you get it from the maw-pell it's good for animals. It's capital for sheep as don't go on well at lambing-time, and for cows too. That as comes from the apple-tree and poplins is the best to hang up in the house on New Year's Day for good luck through the year; but a many people use any that comes first. A piece of mistletoe from the haw—*from the haw*, sir—chopped in pieces and given to a cow after calving, will do her more good nor any drench you can give her." Sir Thomas Browne mentions the practice of thus administering it among his "Vulgar Errors," but at least it is one not likely to be attended with evil consequences.

The reason of the exclusion of mistletoe from church decoration may be gathered from what has already been said, and to this we must add, that its appearance there might be likely to suggest something more ardent than "the kiss of peace." But in hall and cottage alike the mistletoe reigns supreme at this season, and in London and other great towns the artisan spends a small portion of his Christmas wages in the purchase of a few sprigs wherewith to decorate his house and bring good luck to its inmates. From Herefordshire and Worcestershire between 200 and 300 tons of mistletoe are annually exported, and during the present week nearly every train from the West Midland district bears with it a truck-load of branches, fraught with we know not what romance, and bright with berries wherein is contained the destiny of the coming year.

THE MIDNIGHT SKY*

SURELY if ever there were an Astronomy made easy, here it is: if ever there were a sensible Christmas present for a boy, here it is. In fact, it is impossible to commend Mr. Dunkin or the Religious Tract Society too highly for the work which they have jointly produced. It is an honest, scientifically sound, beautiful book, with appeals both to the eye and the mind: one in which the magnificence of the heavens and the deep teachings of modern science go hand in hand, until at last the unscientific reader will certainly find himself deeply interested in the discussion of questions, and the following-out of reasonings, which but a few short years ago were generally supposed to furnish day-dreams to solitary astronomers, who dwelt in towers far removed from the ken of their fellows, and still further removed from their pursuits and interests.

That such a state of things is past and gone, and that the glories of the firmament are now eagerly revelled in by thousands, ay, and even tens of thousands, is in the main owing to the publication of such books as the "Midnight Sky," and the many handy series of star-maps which Mr. Proctor and others have produced.

The book contains carefully drawn views of the midnight sky, at London, looking north and south, for every night in the year. These views are accompanied in each case by an index-map giving the names of the principal stars. In order that these maps may be utilised at any other hour than midnight, Mr. Dunkin has provided the observer with a tabular statement which gives at one view the hour and month when each diagram of the series is available for comparison with the sky. The descriptions appended to these maps are clearly written in a style which will not be found beyond the comprehension of the least scientific reader. Mr. Dunkin next gives a description of the midnight sky of the southern hemisphere, in the months of February, May, August, and November. Following these articles and star-maps, we find an interesting account of the constellations, general notes on the milky way, the magnitudes, scintillation and colour of the stars, analysis of solar and stellar light, the observatories in the southern hemisphere, and remarks on nebulæ and clusters. Notes on the sun, moon, and earth, the major and the minor planets, succeed, and the work is concluded by a full account of meteors and shooting stars, a copious index serving to give increased usefulness to the book.

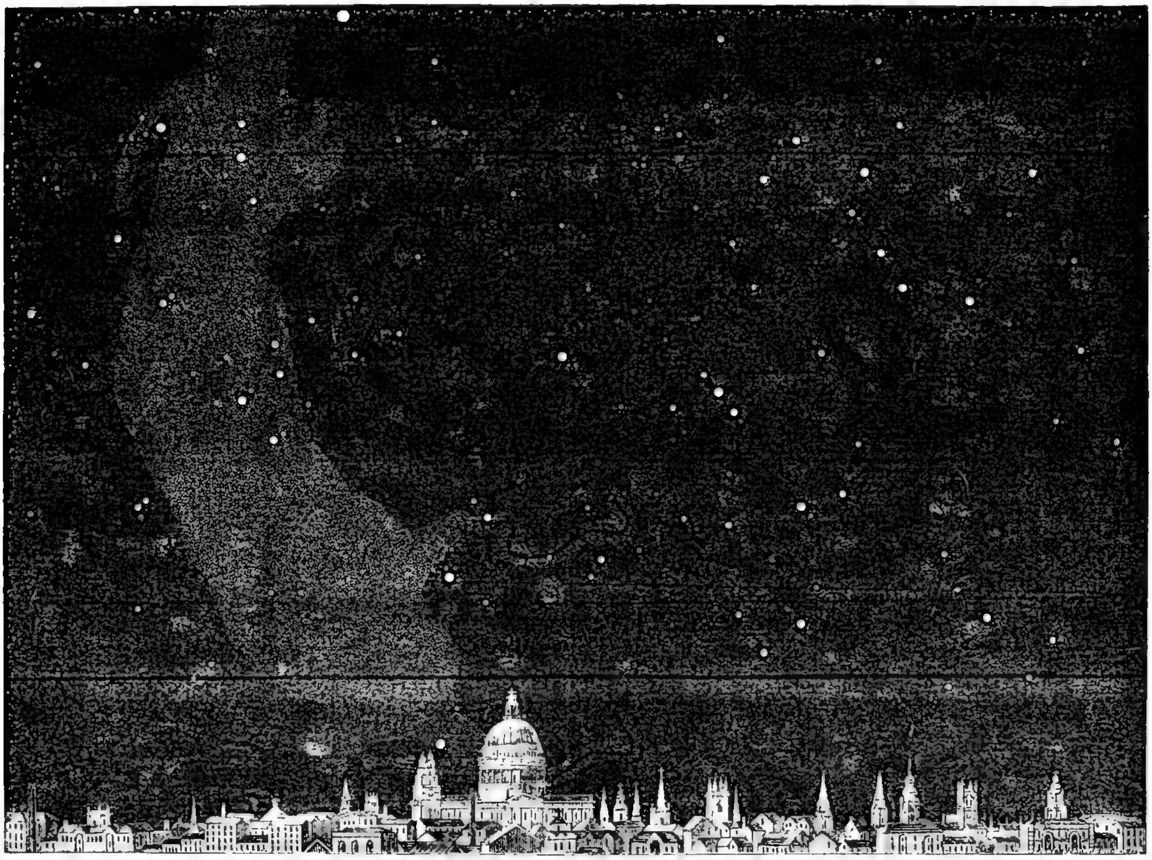
The Religious Tract Society has done wisely in entrusting the writing of these familiar notes to an astronomer of such high ability as Mr. Dunkin. Not only have we at once a guarantee of correctness in the facts themselves, but there is insured that freedom of style which only an intimate acquaintance with a subject can give, and, in the case of such a far-reaching and intricate science as astronomy, this consideration is of high importance—witness the flabby books written by incompetent men.

In the latter part of the work, which forms a sort of treatise on astronomy, Mr. Dunkin dwells among other matters on solar eclipses, and gives several very interesting anecdotes connected with them which we do not remember to have seen in print before. In the notes on the sun we detect a little hasty writing, which the author will do well to correct in subsequent editions. In the first place the hydrogen is the sun's chromosphere, is not in a state of *combustion* but of *incandescence;* and M. Le Verrier gets credit for an assertion he made in 1860, which, had Mr. Dunkin printed the context, would be evidently absurd, according to our present knowledge. Father Secchi is credited too with having proved satisfactorily the hollow

* "The Midnight Sky." Familiar Notes on the Stars and Planets. By Edwin Dunkin, F.R.A.S., Royal Observatory, Greenwich. Thirty-two Star-maps and other Illustrations, pp. 326. Religious Tract Society.

structure of sun spots, the fact being that Father Secchi has only clumsily followed in the footsteps of others, and has contradicted himself in the process. We might have expected also a little notice of the bearing of the recent work on the theories of the constitution of the sun and with the timid, feeble, faith-lacking tone of many of the more modern orthodox.

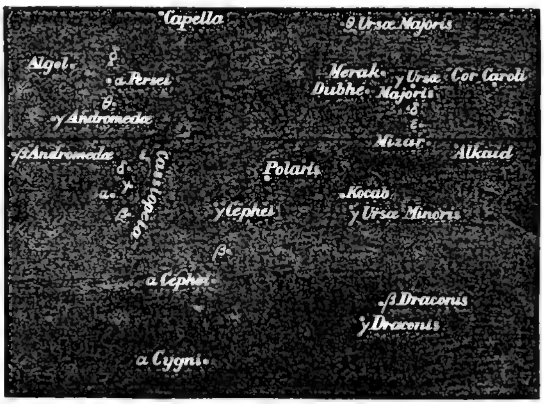
Besides the star-maps and key-maps, specimens of which we give, there are excellent telescopic views of the star-cluster in Perseus, the moon, comets, &c., and drawings of Sir



NORTHERN HEAVENS AS SEEN FROM LONDON JANUARY 15 (MIDNIGHT)

stars, and of the new theory, based on that work, which has been put forward.

But enough of criticism. No; we have a little more. We think the last chapter out of place, or at all events very unhappy in its treatment, and we believe that Bishop Hall would have thought so too, and we commend the following extract from his Contemplations* to the attention of the Religious Tract Society:—"Human learning, well improved, makes us capable of Divine. There is no knowledge whereof God is not the author: He would never have bestowed any, that should lead us away from Himself. *It is an ignorant conceit, that inquiry into nature should make men atheistical.*" This remarkable passage contrasts strongly



KEY-MAP

W. Herschel's forty-foot reflecting telescope, the Royal Observatory in Flamsteed's time and to-day, the great Equatorial in the Royal Observatory, and of many more interesting subjects either astronomical in themselves or connected in some way with the science. From these we have chosen an exquisite wood-cut representing a meteoric shower as seen off Cape Florida. We know no better way of giving our readers an idea of these splendid phenomena visible so rarely, than by placing this plate before them. With our ordinary experience of meteor showers, even including the brilliant one of 1866, it is almost impossible to believe that such a splendid sight should ever have been realised, but the many published accounts which we have, leave no doubt that here also Nature had beggared description.

METEORIC SHOWER AS SEEN OFF CAPE FLORIDA

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Variety and Species.

IN a recent number of NATURE I noticed an extract from a paper read before the Literary and Philosophical Society at Manchester, on the subject of variety as distinguished from species. The author suggests the question, "where does species end, variety begin?" From experiments, he finds that the colours in different parts of the wings of insects treated with, in some cases become toned down to a more sombre hue, in others become mixed with the adjoining colour, and that they are in every case smaller. May not these differences be attributed to the effects of a confined and unnatural life. I myself well recollect rearing a Drinker Moth when a boy at school, and obtaining a small, dull-coloured specimen, instead of an insect whose rich brown wings rival in colour those of the well-known "oak-egger." But difference of colour does not constitute the only variety which is noticed in *Lepidoptera*, for position of markings and proportions of colour are equally worthy of notice, though not so obvious to the unaccustomed eye. Take, for example, the common six-spot Burnet (*Zygæna filipendula*), of which I know three distinct forms—viz. (1), the ordinary one, with three clear spots; (2), having the spots all connected, forming an ill-defined bar of red down the centre of the upper wings; (3), (a form which I believe to be in general very rarely met with, but of which I have myself captured several specimens), having the red markings of (1) supplied by those of a pale yellow, in both upper and under wings. Now, since these were all captured in one field where the three forms are comparatively common, may it not be more than probable that the difference is not to be denominated a variety, but to be a natural dissimilarity of form; not to be attributed to any physical difference of circumstances, previously to the attainment of the state of "imago," but to a purely natural and unassisted cause? A white horse is not considered a variety because his sire was a bay, nor is the whiteness of a bullock considered a *lusus naturæ* if born from tawny parents. I hope to be able to make experiments during the following year, which may perhaps lead to more conclusive results on this subject.

F.

Cuckow's Eggs

I TRUST that, although some time has elapsed since Professor Newton's very able paper on Cuckows' eggs appeared in NATURE, I am not too late to offer a few observations on it, the more so as I have always taken great interest in the breeding of the cuckow. I cannot quite agree with Professor Newton that cuckows' eggs *as a rule* are subject to great variety. The eggs of the Great Spotted Cuckow (*Oxylophus glandarius*) are certainly not subject to much variety; for in a large series from Africa and Spain I have found them closely resemble each other. Of our common cuckow (*Cuculus canorus*) abnormally coloured eggs have several times come under my observation, but I consider them as of very rare occurrence, and in several large series I have seen, but few have struck me as differing much from the usual type.

Of those I possess in my own collection, the most peculiar variety is a large egg, the ground colour of which is a dirty grey, sparingly spotted and blotched with light brown, and somewhat resembling some varieties of the eggs of the Garden Warbler (*Sylvia hortensis*). This egg was found by the late Mr. E. Seidensacher, of Cilli, Styria, in a nest of the creeper (*Certhia familiaris*), with four eggs of the foster-parent, and was sent to prove that the cuckow must have deposited her egg with her bill, as the nest of the creeper was so placed that she could only have got her head in. A German friend of mine, residing near Coblentz, sent me, for inspection, last year, a most peculiar cuckow's egg, which reminds one of that referred to by Salerne. This egg was rather large for that of a cuckow, and of a uniform bluish green colour. He did not, however, state in what nest it had been found.

My own experience in field natural history leads me to confirm the opinion given by Professor Newton, that the same female produces eggs which closely resemble each other; but at the same time I have not found that the same cuckow generally makes use of the same species of bird as nurse for her offspring, and in this I am borne out by several field naturalists with whom I have worked.

My friend at Coblentz wrote to me some time ago, stating that he had observed that the same female cuckow generally produces similarly coloured eggs, and that he had found in a nest of *Turdus merula* a peculiar and abnormally coloured egg of the common cuckow, closely resembling that of the common bunting (*Emberiza miliaria*), and shortly after found in a nest of the Robin (*Sylvia rubecula*), situated close to the blackbird's nest above referred to, another similar cuckow's egg. He further states that the cuckow is not a common bird there, and that he had good reasons for supposing that the two eggs were produced by the same female; also that in 1867 the same thing occurred, when he found peculiarly coloured cuckows' eggs in nests of the Chiffchaff and Willow-wren.

As far as my own experience goes, I cannot testify to the correctness of Dr. Baldamus's theory, as amongst all the cuckows' eggs I have collected, I find scarcely any that resemble those of the foster-parents. I have now before me eggs of our common cuckow taken with the following species, the eggs of which I have with each cuckow's egg, viz.: *Sylvia arundinacea, S. rubecula, Certhia familiaris, Emberiza hortulana, Sylvia palustris, S. cinerea, Motacilla alba*, and *Accentor modularis*, none of which, excepting that found with the eggs of *Sylvia cinerea*, bear any resemblance to the eggs of the foster-parent. The eggs of the American cow bunting (*Molothrus pecoris*) which, like our cuckow, entrusts its offspring to foster-parents, seldom, I believe, resemble those of the foster-parent, and in the instances that have come under my own observation I have found them to differ very widely from the foster-parent's eggs. On the other hand, the eggs of the Great Spotted Cuckow (*Oxylophus glandarius*) are so strikingly similar to those of the common Magpie, in whose nests they are generally placed, that it is often difficult to distinguish them except by handling them, the texture of the shell being very different from that of the magpie's egg. In Spain they are, however, occasionally found in the nests of the Azure-winged Magpie (*Cyanopica Cookii*,) from the eggs of which bird they differ very much.

H. E. DRESSER

Physical Meteorology

IN Mr. Balfour Stewart's suggestions (NATURE, p. 192) he refers, as an illustration of his method, to a frequently falling barometer in the centre of a cyclone while air is rushing in from every side, and asks, "What can carry off the air if there be not an ascending current in the very heat of the cyclone?" I would therefore ask his consideration of the grounds on which, as I believe, such an "ascending current" *must* there take place on the simple principle that great heat has been evolved.

It is well known—(1) That long-continued and heavy rainfall takes place in any area of low pressure with higher pressure outside of it. (2) That the greater part of the rain which falls, during storms, descends in the front part of the atmospheric depression which attends the storm; and (3) That the rainfall is *proportional* to the suddenness and extent of the fall of the barometer. Now, though mere *sequence* does not *prove* a connection as "Cause and Effect," it certainly *suggests* it if the supposed cause be adequate to produce the effect. Let B represent a certain weight, the latent heat of vapour at (10° Cent.) 50° Fahr. is (Regnault 599°.5 Cent.) = 1079° Fahr. But specific heat of air is to that of water as 0.2375 : 1 (Regnault). Consequently B of vapour condensed would heat B of air $\left(\frac{1079°}{0.2375}\right)$ 4543° of Fahr.

When a warm and very moist equatorial current meets and intermingles with a cold polar current (from the known laws of vapour) the column of air, thus mixed, must deposit a certain amount of moisture. Let us assume the mixed stream to be about 1,000 feet in thickness, and that $\frac{1}{10}$ of an inch of rain falls suddenly on the surface. 1,000 cubic inches of air weigh about 310 grains, and $\frac{1}{10}$ cubic inch of water about $25\frac{1}{4}$ grains. Consequently, the latent heat of this $\frac{1}{10}$ inch of rain would heat the air of the 1,000 feet column $\left(\frac{4543° \times 25\frac{1}{4}}{310}\right)$ 370° of Fahr. which *must* occasion an enormous ascending current of air, thereby producing a sudden diminution of the pressure at the surface, and causing a large influx of air to restore the equilibrium.

We know that "whirlwinds" arise from "local heating" (as in dust-storms or prairie-fires); hence a like effect must result from such local evolution of heat through the condensation of atmospheric vapour, and the heated column of air will ascend (as a whirlwind in the upper strata) *before* the like effects are produced at the surface.[1] In his remarks on the great storm (at Nassau, October 1866), Captain Chatfield observed, "that (during the calm) while the vortex of the storm was passing over the harbour, the atmosphere was most oppressive, and the clouds in the zenith appeared to be revolving rapidly." Under certain modifying circumstances, the same *vera causa* will, I believe, account satisfactorily for the phenomena of "hail-storms," "water-spouts," &c. But I am unwilling to trespass too much on your space.

Glenville, Fermoy HENRY HUDSON, M.D.

A Cyclone in England.

IT is so seldom we get a cyclone so well developed in these latitudes, that I have thought the following observations would interest the readers of NATURE.

Noon.	Barometer,	29.678.	Wind,	S.S.W.	Estimated force,	4
4 P.M.	,,	29.304.	,,	S.W.	,,	9
6 P.M.	,,	29.205.	,,	W.	,,	10
9.40 P.M.	,,	29.342.	,,	W.N.W.	,,	9
11 P.M.	,,	29.391.	,,	N.W.	,,	7

It will be observed the wind began to freshen from the S.S.W. with a falling barometer; it then veered to S.W., W.S.W. to W., the barometer falling the whole time. When the wind arrived at W. the storm was at its height and the barometer a minimum. The wind then veered W. by N., W.N.W. to N.W., gradually becoming less violent, and the barometer rose during that time. The storm lasted about twelve or fourteen hours.

From the above, I deduce that Plymouth must have been in the southern half of the cyclone which travelled eastward; hence, probably, more damage must have been done further north than here.

I should feel obliged by any reader of NATURE living in the North or East of England, giving the results of his observations during the storm. F.R.A.S.

Plymouth, 17th December, 1869.

Lectures to Ladies

I HAVE only just seen the letter in NATURE, signed "M.A.B.," on the subject of the hour chosen for lectures to ladies. I most sincerely hope that the morning hour will be continued. It is certainly to be regretted if this arrangement is inconvenient to ladies engaged in teaching; but to the far larger number who are not so engaged, any other hour would be prohibitory.

In addition to the constant inconvenience entailed on ladies by the necessity (or supposed necessity) of their being "fetched and carried" every time they go out after dark, all ladies living ordinary lives in quiet homes, know very well that it behoves them to get their "occupations" done in the day-time, and that if they began attending courses of lectures in the evening, their fathers, husbands, and brothers would be apt to raise a pretty forcible outcry against the advance of female education.

If I might venture to make a suggestion, it would be that South Kensington is a very long way from everywhere else, and that a more central situation would add very much to the convenience of those who come from a distance. I am sure that no one who attended Professor Huxley's course of lectures just concluded, begrudged the time and trouble it cost them to get there, or thought it anything but well bestowed; at the same time a shorter and more manageable expedition would be a great boon to many. M. T. G.

NOTES

THE Gold Medal of the Royal Astronomical Society has, we are informed, been this year awarded to M. Delaunay, one of the greatest of living mathematicians and astronomers, for his many important investigations. We are sure that English astronomers will hail this award with the liveliest satisfaction.

THE question of Meteorological Standards is, we learn, now occupying the attention of the Royal Society Council. We may hope, therefore, that the revision which has so long been needed will now take place.

THE Lecturers named for the Friday Evening Meetings at the Royal Institution, before Easter, are Prof. Tyndall, F.R.S., Prof. Odling, F.R.S., Prof. Ruskin, Dr. W. B. Carpenter, F.R.S., Mr. W. K. Clifford, Colonel Sir Henry James, F.R.S., Mr. E. J. Reed, C.B., Chief Constructor of the Navy, Prof. Sylvester, F.R.S., Mr. P. W. Barlow, F.R.S, Prof. Rolleston, F.R.S., Prof. Roscoe, F.R.S., and Prof. Huxley, F.R.S. Prof. Tyndall's discourse will be on "Haze and Dust," and will probably be delivered on the 21st of January. Dr. Odling proposes to lecture on "Prof. Graham's Scientific Work;" Dr. Carpenter on "Temperature and Life in the Deep Sea," and Prof. Sylvester on "Chance."

THE Keith Prize of the Royal Society of Edinburgh was awarded on Monday to Professor Tait, for his paper on the rotation of a rigid body about a fixed point.

THE Professorship of Botany in the Royal College of Science, Dublin, is now vacant, Professor Wyville Thomson's resignation having been accepted by the Science and Art Department.

THE following lectures will be given in the course of the present session of the Chemical Society:—On Vanadium, by Dr. Roscoe; on Refraction Equivalents, by Dr. Gladstone; and on the Platinic Ammoniums, by Dr. Odling.

THE subscriptions to the Faraday Monument Fund, received up to Dec. 7, amount to £1,400. The object of the fund is to provide a public memorial to Faraday, and the subscription from one person is not to exceed five guineas.

PROFESSOR CARL VOGT, of Vienna, is actively engaged in the formation of an Anthropological Society for Austria.

DR. S. COULL MACKENZIE has been appointed to the professorship of Hygiene in the Calcutta Medical College.

IN a new quarterly journal devoted to public hygiene, and produced at Brunswick, in Germany, we find a carefully-written article upon English institutions for hygiene, and English factories. There are also contributions upon army hygiene, barrack reform, and drainage. The journal is edited by Prof. Riclam, of Leipzig.

THE Argenteuil Prize has been awarded by the Academy of Medicine of Paris in the following way:—To Mr. Corradi, of Florence, 5,000 francs; to MM. Mallez and Tripier, 2,000 francs; to M. Reliquet, 1,000 francs.

THE General Secretary of the Academy of Vienna has published as a *tirage apart* from the almanack of the Academy, a biographical sketch of Karl Ludwig Freiherr von Reichenbach, who, after a long and distinguished scientific career, died in January last at the advanced age of eighty-one. Dr. Schrötter divides the period of Reichenbach's scientific activity into three parts: the first, that of practical work and exact research, during which he enriched mankind by the discovery of paraffin and creosote; the second, that which he devoted to the study of meteorites, a study in which his enthusiastic mind led him beyond the boundary of accurate science; and, lastly, the time when he gave himself up to the investigation of so-called animal magnetism and the imaginary odic force by which he sought to explain the phenomena he thought he had discovered. Dr. Schrötter rightly concludes, that however far astray Reichenbach may have been led by his odic notions, he earned for himself an honourable place in science, his very errors being those of a highly-gifted man.

WE have received the first part of the volume recording the scientific results of the travels of Baron Claus von der Decken in East Africa, during the years 1857–1865. The materials have been worked up by Peters, Cabanis, Hilgendorf, Ed. von Martens, and Semper, and comprise Mammalia, Birds, Amphibia, Crustacea, Mollusca, and Echinodermata. The part before us is illustrated by thirty-five lithographic plates of great beauty, most of them being carefully and delicately coloured. The second part, which is to contain the Insects and Spiders, has been entrusted to Gerstäcker.

DR. OLDHAM, the president, has communicated to the Proceedings of the Asiatic Society of Bengal some interesting notes on remains found in a Cromlech at Coorg. This Cromlech was opened out by the order of the Chief Commissioner of Mysore, on the Moory Betta Hill, in North Coorg. The relics consist of small earthenware vessels, as well as several beads and tubes bored through, and evidently portions of necklaces. These last are of the colour of agate, and have circles in white around them, with zigzag pattern in white in the centre.

IN the early part of last year Dr. Francis Day, F.L.S., F.Z.S., was commissioned to examine the important subject of the Indian River Fisheries. The result is the publication of an interesting and comprehensive report. Dr. Day's observations were at first directed to the fresh-water fisheries south of Madras. He personally inspected the Coleroon anicuts, and then extended his researches to the places lying between these anicuts and the sea. Dr. Day commenced his examinations with the Cauvery river, which runs a course of a hundred miles in the Tanjore district, where it gives off four large branches. At the island of Serungum, the Coleroon becomes the main channel. At this point an anicut was erected in order to raise the water to a height of six feet by means of a wall or barrier, to which the native name of anicutta or anicut was applied. It was subsequently found necessary to erect a regulating dam upon the head of the Cauvery. This dam consisted of a flooring across the stream, with a slip at each extremity 76 feet long, 2·4 feet above the low or middle portion. On the northern waterway of this anicut there are sluices with vents 8 feet in width. It is stated that when, during the freshets, the fish cannot surmount the dam, they make their way up the river through these vents. During the last few years the decrease of fish in the Coleroon is said to be considerable, though Dr. Day does not entirely endorse this assertion. The most valuable fish in the Coleroon was formerly the oolum, or sable fish, culpea (alausa), palasah, C. and V.; but since the erection of the anicut they have seldom been found. It is asserted that in 1836 the value of the sable fish captured in the river near Trindinopoly was equal annually to about two lacs (£200,000). They were principally taken for their roe; but when in condition they are described as splendid eating. Unless something is done, this fine fish, and others of value, will become extinct in the Coleroon. Dr. Day points out how necessary it is that some means may be tried to enable the fish to ascend the river above the anicut, that the ova may be deposited in sufficiently deep water.

ACCORDING to the *Boston Advertiser*, an upheaval is taking place in the harbour at Machias port, Maine. Vast quantities of water, mud, and stones are being thrown up to the distance of many feet with a loud rushing noise. During last summer this occurrence was frequently noticed.

A GERMAN translation of Mr. Wallace's work on the Malay Archipelago, by Dr. Adolf Bernard Meyer, has just been published by Westermann of Brunswick.

Mr. M. J. Barrington Ward, B.A., F.L.S., Scholar of Magdalen Hall, Oxford, has been appointed Natural History Master at Clifton College.

WE have to record the appearance of the sixth, seventh, and eighth supplementary volumes of the Annals of the Munich Observatory. The first contains the meteorological observations from 1857 to 1866; the second a similar series taken on the Hohenfreissenberg from 1851 to 1864; and the last, a catalogue of 6,323 telescopic stars between + 3° and + 9° declination which occur in the Munich zone observations, reduced to the commencement of the year 1850, together with comparison of the observations of Lalande, Bessel, Rünker, and Schiellerur.

THE second part of the results of the Geological Survey of the West Indies has just been issued under the title "Reports on the Geology of Jamaica." Pending a complete notice of this important volume, we may mention that it contains in its first thirty-seven pages a general description of the physical geography of the island, with outlines of the different formations. The body of the book consists of the details of the lithological structure of the various districts. Appended to the volume is a report by Mr. Etheridge, Palæologist of the British Survey, on the organic remains. He has not only examined and classified these remains, but has also referred them to their equivalents in the cretaceous and tertiary deposits of Europe. Sir Roderick Murchison, in his preface, calls special attention to the interesting results of Mr. Etheridge's work.

THE Royal Irish Academy have voted the following sums of money out of their special parliamentary grant for scientific purposes:—30*l.* to the Rev. Eugene O'Meara, A.M., to enable him to continue his researches on the Irish Diatomaceæ; 30*l.* to H. Hennessy, F.R.S., to determine the molecular condition of fluids and their motion, when in rotation and in contact with solids; 20*l.* to J. Bailey, to carry out experiments on "Flitch Beams;" 20*l.* to B. B. Stoney, to try experiments on riveted joints. All the reports on these subjects will appear from time to time in the "Transactions and Proceedings of the Academy."

A SERIES of very beautiful photographic negatives has been taken of all the more important antiquities in the Museum of the Royal Irish Academy. The Council of the Academy intend to have these printed from, and the prints to be sold both separately and in series.

WE hope shortly to give an article on a new artificial light suitable for the production of photographic enlargements, by Dr. Van Monckhoven.

THE following is the result of the National Sciences Tripos, at Cambridge, in which the examiners were—J. Hooker, LL.D., W. H. Miller, M.A., O. Fisher, M.A., C. Trotter, M.A., and J. B. Bradbury, M.D. Class I. Ds. Watson, Queen's.—Class II. Ds. Kilner, St. John's; Maxwell, King's; Lupton, Trinity; Lees, Trinity; Stirling, Trinity; Simpson, Caius; Calliphronas, Caius.—Class III. Ds. Alliot, Pembroke; Johnson, Jesus; Banham, St. John's; and Colvin, Trinity—equal; Young, Caius. A prize offered by the Professor of Botany has been adjudged to M. J. Barrington-Ward, B.A., Scholar of Magdalen Hall.

WE have received the following note with regard to the Holborn Viaduct:—"The Report of the Engineers, published in the daily papers, entirely endorses the opinion expressed in the note I previously sent you. The only difference between it and my explanation arises from the fact of the insertion in the joints of lead-packing near the outer edge of the stone, which of course exaggerates the evil of a 'concave face.' The variation of temperature which has been dwelt upon as the chief cause of failure is evidently in the opinion of the engineers quite inadequate to account for it."

MR. MELDRUM has kindly forwarded us the following note:—"A strict watch was kept at the Mauritius for meteors during the nights of the 12th, 13th, and 14th November, and the expected shower was seen on the morning of the 14th. Between midnight of the 13th, and 4·40 a.m. of the 14th, 439 meteors were counted at the Observatory, Port Louis, by three observers. Of that number, 427 were seen between 3·20 and 4·40 a.m. Sir Henry Barkly, at his country residence, 7 miles from Port Louis, counted 192 between 3·15 and 4·15 a.m. At my residence, 5 miles from Port Louis, 434 were counted between midnight and 4·40 a.m., by two observers up to 4 a.m., and then by four observers. Between 3·14 and 4·24 we counted 370, and between 3·55 and 4·13, 215. The greatest number seen by Sir Henry Barkly in an interval of five minutes was 33 between 3·55 and 4·0, but he saw only a small portion of the heavens. I have not had time to analyse the observations carefully, but the time of maximum intensity was about 4·09 a.m. The only source of doubt in this subject arises from the circumstance that after 4·15 daylight was setting in. I have no doubt that the radiant point was somewhere within the sickle of Leo, but I am not sure as to its exact position. Most of the meteors shot westward along the ecliptic, through Gemini and Taurus, but others in all directions. The trains of light and the nuclei were generally white, with a slight tinge of green, but all the prismatic colours were seen. The time of duration of the flight was from the fraction of a second up to 6 seconds, and the longest trains about 40°. At one time gleams of light of various forms appeared in Leo. I had a small hand-spectroscope, but the times of duration were too short for using it."

SCIENTIFIC SERIALS

The *Moniteur Scientifique* for December 1 contains a translation of Dr. Williamson's memoir of the late Professor Graham, which appeared in the first number of NATURE, a review of contemporary physics and astronomy, a long notice of M. Paul Champion's work on the ancient and modern industry of China, and the usual accounts of new patents and meetings of scientific societies. The number for December 15 completes the volume for 1869, and gives elaborate tables of contents. The remaining space is devoted to reports of the proceedings of the Academy of Sciences, abstracts of papers, notices of new publications, and an account of the new development of the trade in false autographs.

The *Revue des Cours Scientifiques* for December 11 contains a translation of an essay by Helmholtz on Goethe as a naturalist and a physicist, an article on the boring of Mont Cenis by M. A. Cazin, and a translation of Professor Williamson's memoir of Graham, contributed to our first number. The greater portion of the number for December 18 is occupied by a translation of a paper on the Centenary of Humboldt, read before the Boston Natural History Society by Professor Agassiz. It also contains lectures on Palæontology by M. A. Gaudry, and an important paper on the Mortality of Women in Labour, by Professor Lorain.

In the *Philosophical Magazine* for this month, Mr. C. Tomlinson, F.R.S., gives an account of Van der Meusbrugghe's important treatise on the Superficial Tension of Liquids, in which the movements of camphor on the surface of water are shown to form a particular case of a general theory. Mr. W. H. Preece contributes a proof of the Parallelogram of Forces, and Dr. Odling a note on Condensed Ammonia Compounds. Professor Kengott's Microscopical Investigation of the Knyahynia Meteorite, and M. Abich's paper on Hailstorms in Russian Georgia (both of which are accompanied by plates), are well deserving of attention.

In the *Chemical News* for December 17, Mr. Edwin Smith describes an interesting series of experiments on the Electrical Phenomena of Plants, suggested by a chapter in Becquerel's treatise. A paper read before the Glasgow Philosophical Society by Mr. R. R. Tatlock, F.C.S., on the Estimation of Iodine and Bromine, with special reference to the Analysis of Kelp, is reproduced. Mr. W. T. Suffolk, F.R.M.S., continues his useful articles on Microscopical Manipulation; and Mr. H. C. Sorby, F.R.S., describes the application of the Spectrum Microscope to the Valuation of Wines. In a paper on the Constitution of the Compounds of Sodium, Mr. J. A. Wanklyn, F.C.S., adduces new arguments in support of his opinion that the metal sodium had a polyvalent character. The books noticed in this number are Dr. Bence Jones's Memoir of Faraday, and a treatise on the Leclanché Battery. Correspondence from Dr. Mennier and Dr. J. H. Gladstone, and Chemical Notices from Foreign Journals, make up the rest of the number.

A Paper by M. Felix Plateau, on the Flight of the Coleoptera, read before the Physical and Natural History Society of Geneva, in September last, has just been published in the *Bibliothèque Universelle et Revue Suisse*. The conclusions arrived at are as follows:—(1), The difference of flexibility between the two edges of the wing are not sufficient to account completely for the phenomena of flight. (2), The wing makes a wide angle with the plane in which it moves. (3), It is deflected more rapidly than it is elevated. (4), The extent of surface of the wing is greater in the movement of deflection than in the movement of elevation. The influence of the elytra, their form and mode of action, as well as some other considerations, are reserved for a memoir which the author hopes to publish shortly.

ASTRONOMY

Oppolzer communicates to the *Astronomische Nachrichten* the following elements of Comet II., 1869:—

$$\tau = \text{Oct. } 9{\cdot}266 \text{ Berlin mean time.}$$

$$\left.\begin{aligned}\pi &= 139^\circ\ 1'\ 13''\\ \Omega &= 311^\circ\ 27'\ 51''\\ \iota &= 111^\circ\ 26'\ 40''\end{aligned}\right\}\text{Mean Eq. 1869–70.}$$

$$\log.\ q = 0{\cdot}09014^\circ$$

Professor C. H. F. Peters, of Clinton, N.Y., has discovered still another new planet, 9·7 mag., the elements of which are as follows:—

$$\tau = 1869, \text{ Oct. } 0{\cdot}0 \text{ Berlin mean time.}$$

$$\begin{aligned}M &= 338^\circ\ 1'\ 47{\cdot}7''\\ \pi &= 53^\circ\ 8'\ 20{\cdot}8''\\ \Omega &= 5^\circ\ 3'\ 52{\cdot}2''\\ \iota &= 8^\circ\ 9'\ 59{\cdot}4''\\ \phi &= 16^\circ\ 43'\ 30{\cdot}2''\\ \mu &= 808''32\\ \log.\ a &\ \ 0{\cdot}428281\end{aligned}$$

SOCIETIES AND ACADEMIES

LONDON

Royal Astronomical Society, December 10. — Second Meeting of Session. Admiral Manners, president, in the chair during the early part of the meeting; afterwards (the president finding his health not sufficiently restored to enable him to remain), Mr. De la Rue, F.R.S., vice-president, took the chair. The minutes of the last meeting were read and confirmed, and thirty-two presents announced, including a magnificent representation of the solar spectrum from France (showing the part beyond the violet end), presented by Mr. Ladd. Mr. Williams, the assistant secretary, then read a series of extracts from an elaborate work on Chinese Astronomy, upon which he has been engaged during the last three years. He exhibited in a very complete and lucid manner the Chinese mode of reckoning time by cycles of sixty years, the several years of each cycle being indicated by certain characters called Kea Tsze. He then showed how any year in ordinary chronology, whether B.C. or A.D., can be represented in the proper cycle, and in its right place in that cycle. He described the division of the heavens into thirty-one parts; three, called "Yuen," of large size; the remainder, called "Suh," representing lunar houses, and very irregular in extent, both from east to west and from north to south. While one, for instance, extended north and south from Perseus to Canopus, another consisted mainly of a few stars in the head of Orion. Other extracts exhibited the correctness of the positions assigned by the Chinese to the equinoxes and the solstices, and the evidence their estimates give respecting the date at which their observations were made. He mentioned *inter alia* that the Metonic Cycle had been known to the Chinese astronomers 2,000 years before Meton's day. The occurrence of the names of our modern asterisms in Chinese records must not be held to indicate the antiquity of our constellation-figures, because it cannot be doubted that the Jesuits taught the Chinese these new names. In fact, the Chinese were led to remodel their system of astronomy according to the instructions of the Jesuits—a misfortune, perhaps, since, al hough the old system of astronomy had had the disadvantage of being inexact and scarcely intelligible, the change destroyed many of the clues by which we might have found clearer ideas as to what the Chinese astronomers really meant to record.—The Astronomer Royal indicated his high opinion of the value of such researches as those in which Mr. Williams had been engaged. Astronomy is the science which of all others brings most together the past, the present, and the future, and, therefore, all studies of long past eras, even though the astronomical observations then made were comparatively inexact, cannot but have a high value. Mr. Stone, F.R.S., called attention to the general value of the matter brought before the society's notice by Mr. Williams, but expressed his regret that the Chinese records named only the day on which any phenomenon was observed. Mr. De la Rue then mentioned that the greater part, if not all, of Mr. Williams's work, would be printed in the Society's Memoirs.—The Astronomer Royal described an arrangement for correcting atmospheric chromatic dispersion, even simpler than those he had before devised. It had occurred simultaneously to himself and to Mr. Simms, the optician, and consists simply in giving the eye-glass of an eye-piece such a motion that while the face towards the field-glass presents an unchanged curvature, the other face (plane) is slightly inclined. This is clearly equivalent to the addition of a prism to the eye-glass, only there is no loss of light, as there would be were a separate prism added. The new eye-piece will serve also to correct errors in the centreing of an object-glass.—Professor Cayley discussed certain geometrical relations connected with the problem of determining the place of a body revolving round the sun, from three observations. He remarked that each observation shows that the body lies on a known line. If we take these three lines in space, what the problem really requires is, that we should determine the position of a plane passing through the sun, and intersecting these lines so that a conic through the points of intersection should have the sun in its focus, and the areas between vectorial radii to the points proportional to the two observed time-intervals. He then considered the locus of the orbit-pole, (1) for an assumed eccentricity, (2) for an assumed period, on a stereographic projection of a portion of the sphere—equal in extent to one half, but not actually a hemisphere. The *loci* for poles to *real* orbits—that is, orbits having all three points on one branch—exhibit a singular figure, the true locus having *points d'arrêt* on the bounding-lines of the half-sphere of projection. In answer to questions by the Astronomer Royal, Mr. De la Rue, and Mr. Stone, Professor Cayley indicated that his paper was intended rather as a contribution to the geometry of the problem than to its practical solution.—Dr. Balfour Stewart then read a paper on terrestrial magnetism. After referring to the views he has already published respecting the earth's magnetic character, he indicated his belief that the zodiacal light is a phenomenon of terrestrial magnetism, owing its existence to the magnetic effects produced by the upper air-currents (the counter-trades); these effects not being recognisable, of course, in ordinary observations. He suggested also that the motion of the tidal wave might account for the magnetic variations, whose period corresponds to the lunar diurnal motion. The Astronomer Royal remarked on the complexity of the whole problem of terrestrial magnetism, which he characterised as hardly belonging to the class of subjects usually dealt with by the Society.—Mr. Proctor gave a brief sketch of a new theory of the Milky Way. He regards the galaxy as neither a cloven disc, as Sir W. Herschel opined, nor a flat ring as Sir J. Herschel has suggested, but a spiral of a figure which he indicated as serving to explain all the most striking peculiarities of the Milky Way, as seen upon the heavens.—Another paper by Mr. Proctor, on Great Circle Sailing, and a letter from Lieut. Tupman about the November meteors as seen in Egypt, remained unread owing to the lateness of the hour.

Geological Society, December 8.—Professor T. H. Huxley, LL.D., F.R.S., president, in the chair. The following communications were read:—1. "Notes on the Brachiopoda hitherto obtained from the Pebble-bed at Budleigh Salterton, near Exmouth, in Devonshire," by Thomas Davidson, Esq., F.R.S., F.G.S., &c. The author first described the general characters, and discussed the opinions that have been put forward as to the origin of the pebbles forming this bed. Nearly forty species of Brachiopoda have been obtained from them. The fossils contained in the pebbles have been regarded as of Lower Silurian age; the author considered the great majority of the Brachiopoda to be Devonian. The species identified with Silurian fossils are:—*Lingula Lesueuri* (Rouault), *L. Rouaulti* (Salter), and *L. Hawkei* (Rouault). The species regarded by the author as undoubtedly Devonian (*i.e.* either previously described from Devonian deposits or associated with such species in the same pebble) are twelve in number, namely:—*Spirifer Verneuilii* (Murch), *S. macroptera* (Goldf.) *Athyris budleighensis* (sp. n.), *Atrypa* (*reticularis?*), *Rhynchonella inaurita* (Sandb.), *R. elliptica* (Schnurr.), *R. Vicaryi* (sp. n.), and two undetermined species of *Rhynchonella*, *Streptorhynchus crenistria* (Phil.) *Productus Vicaryi* (Salt.), and an undetermined *Chonetes*. Eight species occurring in the same rock, three of which have been doubtfully identified, are considered by the author to be probably Devonian. The species supposed to be determined are:—*Orthis redux* (Barr.) and *O. Berthosi* (Rouault), Silurian; and *Spirifer octoplicatus* (Sow.), Devonian and Carboniferous, but possibly identical with the Silurian *S. elevatus* (Dalm.) The others are two new species of *Orthis*, and a new *Rhynchonella* (?), and an undetermined species of *Terebratula* (?) and *Strophomena* (?). Finally, the author noticed fourteen species (all new, except *Orchis pulvinata*, Salt.) only known from these pebbles, but which were stated to possess a Devonian *facies*.—Mr. Etheridge agreed with Mr. Davidson as to his determination of the species. He had, however, examined the extensive collection of Mr. Vicary, and, from their general *facies*, he was inclined to assign them to the Middle Devonian and Carboniferous beds. The attribution of the fossils to Upper Llandovery beds was founded on the presence of *Lingula crumena*; but he thought he could give some clue to the locality from which the pebbles had been derived. It had first, from the lithological character of the pebbles, as well as from the fossils, been thought that they were of Lower Caradoc age. He himself assigned the position of the rocks from which the pebbles had been derived to the Hangman group of North Devon. At Anstis Cove, Mr. Tawney had found a series of the same class of fossils in a matrix exactly like that of the pebbles. He had examined the spot, and there recognised an extension of the sandstones of North Devon (the Hangman Grits) on the south coast, and certainly, so far as lithological character is concerned, the rocks are the same as the pebbles. It did not, however, follow that the pebbles came from that particular district, but probably from the denudation of the large tract of country of Devonian age to the north. There are, however, Silurian species in the pebbles, and these he would refer to the denudation of rocks in an area mainly to the south of what is now the Devon coast. The fauna at Budleigh Salterton is essentially British, and not French, though some few species are common to both areas. The bivalves, indeed, were hardly known in France. On the whole, he concluded that the fossils in the pebbles were Devonian, with a slight admixture of Silurian and probably Carboniferous forms, derived from rocks at no great distance from the spot where the pebbles are found.—Professor Ramsay pointed out that in conglomerates it might be expected to find pebbles of rocks of various ages. He commented on the difficulty palæontologists seemed to labour under in determining a fossil if it came out of a pebble instead of from a rock the position of which was definitely known. He adverted to the statement that the beds containing the pebbles had been deposited in the New Red Sandstone sea, whereas Mr. Godwin-Austen had regarded the New Red deposits as formed in large inland lakes; and the local character of the beds supported this latter view.—Mr. Prestwich was glad that some other source had been suggested for the quartzite pebbles. He had found somewhat similar quartzites between Lisieux and Cherbourg, in France.—The President observed that he would like to see the rise of a new race of palæontologists, relying simply on zoological characteristics, and not on geological position. A considerable simplification of our classification would probably result.—Mr. Etheridge briefly replied.

2. "On the relation of the Boulder-clay without Chalk of the North of England to the Great Chalky Boulder-clay of the South," by Searles V. Wood, jun., Esq., F.G.S. The author described the Yorkshire glacial clays as of two kinds—the lower, containing chalk debris, and belonging to the uppermost member of the glacial series in eastern and east-central England; the upper containing chalk sparingly in its lower part, and gradually losing this upwards. On the coast the latter occurs only north of Flambro'. He stated that, palæontologically, the lower and middle glacial deposits closely agree with the crag, and are quite distinct from the deposits at Bridlington, which he placed immediately above the "Great Chalky Clay." The absence of chalk debris in the deposit north of Flambro' has been regarded as evidence of a drift from north to south; but the author stated that the purple clay without chalk extends over much of the north-eastern part of the Wolds, from the sea-level to an elevation of 450 feet, and that outliers of it occur at intervals along the Holderness coast-section as far as Dimlington, forty-two miles south of the northern limit of the Wolds. In the direction of Flambro' and York the clay was said to be destitute of chalk, which would not be the case had the Wolds formed a sea-shore causing a drift from the north to pass either to south-east or south-west. The author described the characters of the great chalky boulder-clay in the eastern and central counties of England, and maintained that the chalk found in it (equal, according to him, to a layer of at least 200 feet over the entire Wold) could only have been detached by the agency of moving ice, which he believed to have covered nearly the whole Wold for a long period. The author stated that boulders of Shap Fell granite are confined to the deposit of clay without chalk; and discussed the means by which they could have been distributed. He ascribed their dispersion to the agency of floating ice during an adequate sub-

mergence of the district. He supposed them to have passed from Shap Fell by what is now the pass of Stainmoor. Thus he ascribed the formation of the "great chalky clay" to the extrusion from the sea-foot of a great sheet of ice, of materials abraded by the latter, the land being depressed 600 to 700 feet below its present level; and that of the clay without chalk and with boulders of Shap Fell granite to deposition during a period of much greater depression (about 1,500 feet), throughout which the sea bore much floating ice. He considered that the "great chalky clay" indicated a long period during which the land, with its enveloping ice, remained stationary, and that during this period, when intense cold prevailed, the arctic fauna of Bridlington became established. He thought that the recommencement of subsidence was indicated by the reddish-brown or brownish-purple sediments of Holderness, in which some chalk occurs. He then indicated the species of mollusca which have occurred in the purple clay without chalk about Scarbro' and Whitby, all of which were said to belong to existing forms, and thus be in accordance with the date assigned by him to that deposit. The molluscan fauna of Moël Tryfane was referred to by the author, who stated that he regarded it as belonging to the period of emergence from the deepest depression during which the clay without chalk was assumed to have been deposited, *i.e.*, to the earliest part of the post-glacial period, to which the stratified drifts of Scotland are referred by Mr. A. Geikie. Mr. Gwyn Jeffreys had found the shells of Kelsea and elsewhere in Yorkshire to be mainly arctic; and Mr. Prestwich, in his paper on the boulder-clay near Hull, had first pointed out their glacial character. In the late dredgings in H.M.S. *Porcupine* several of the species before known as fossil at Bridlington, but not as existing in the British seas, had been discovered. In fact, he believed that the Bridlington species, with but few exceptions, had now been found in the British seas. Similar species had also been found in the boulder-clay in Scotland. Prof. Ramsay was pleased to find the author's views so closely correspond with his own published some years ago as to the glacial phenomena of North Wales, though based on another part of the country. He thought that shells might be found by careful search in the low-lying boulder-clay in other places than those enumerated, as they had been discovered in the western part of England. Mr. Prestwich, though inclined to accept the divisions of the boulder-clay in Yorkshire as suggested by the author, was not so clear as to his divisions in the south. He thought the presence of chalk in the clay might be traced to the contiguity of the outcrop of the chalk stratum. The shells being to a very great extent recent, the grouping might be due to accidental or local circumstances. The Chillesford clays, in his opinion, mark the commencement of the great glacial period. Mr. Etheridge suggested that *Nucula Cobboldiæ*, *Cardita similis*, and some other shells not found in the British seas, proved the arctic character of the Bridlington fauna. Sir Charles Lyell remarked that if the fauna of the lower and middle glacial really corresponded so closely with that of the crag, it afforded a strong argument against their being of the same age as the Bridlington beds. Perhaps, eventually, some palæontological connection might be traced throughout the series, and a chronological scale established. The President suggested a difficulty in the marine transport of ice from Shap Fell to Bridlington, not only from the wind blowing rarely in the necessary direction, but from the current caused by the great submerged ridge also tending to carry any bergs in another direction. He thought the transport by sheet-ice more probable. The Rev. J. L. Rome had traced the Shap granites over the valley of the Eden, across Stainmoor, to the Yorkshire side. There might have been difficulties in their transport, but there they are. Though they were found in Teesdale, yet the intervening ridge of millstone-grit, 2,000 feet, had prevented them finding their way into Swale Dale. Mr. Searles V. Wood, jun., stated that he had relied on Mr. Gwyn Jeffreys's works for his classification of the shells as being arctic or otherwise. He regarded the succession of the various members of the glacial series as well established, and as borne out also by the molluscan remains. He utterly repudiated the notion that the Chillesford, Bridlington, and Kelsea Hill beds were on the same horizon. He believed the whole of the Scotch beds to be newer than those of England. He quoted Professor Phillips as suggesting a change in the elevation around Shap Fell since the dispersion of the boulders, and offered as his own explanation of the hypothesis, that the passes by which the boulders travelled were those which, though at the higher levels, were the soonest freed from ice. He thought that the direction of the current was influenced by other causes than the general trend of the rocky dividing ridge.

The following specimens were exhibited to the meeting:—Fossiliferous Pebbles from Budleigh Salterton, exhibited by Professor Tennant and R. Etheridge, Esq.

Zoological Society, December 9.—Dr. E. Hamilton, V.P., in the chair. The Secretary read a list of the more remarkable of the recent additions to the Society's menagerie, amongst which were particularly noticed two gibbons (*Hylobates lar*), deposited by G. S. Roden, Esq. An extract was read from a letter addressed to the Secretary by Capt. G. E. Bulger, C.M.Z.S., correcting an error in a former paper by him on the birds observed at Wellington, in the Neilgherry Hills, published in the Society's Proceedings. Professor W. H. Flower, F.R.S., gave some account of the external characters of the fin-whale, recently stranded in Langston Harbour, near Portsmouth, which he considered referable to the species usually called *Balænoptera musculus*. Mr. Flower concluded his remarks with a sketch of the species of the Balænoid, or whalebone-producing, whales, which occur in the British seas. These, according to our present knowledge of them, appear to be six in number, namely:—*Balæna biscayensis*, *Megaptera longimana*, and *Balænopteræ musculus*, *Sibbaldii*, *laticeps*, and *rostrata*. A communication was read from Surgeon Francis Day, F.Z.S., on the fresh-water fishes of Burmah, being an account of the specimens of this class of animals obtained during a recent inspection of the fisheries of Pegu, and during a short visit paid to the capital of Upper Burmah. A second communication was read from Surgeon Francis Day containing the third part of his critical notes on the fishes of the Calcutta Museum. Mr. G. French Angas gave descriptions of twelve new species of land-shells belonging to different subdivisions of the family *Helicidæ*, from the Western Pacific Islands. Mr. P. L. Sclater read a list of the birds that had bred in the Gardens of the Society during the past twenty years. The total number of species enumerated in this list was 108. Mr. R. B. Sharpe pointed out the characters of a new kingfisher belonging to the genus *Tanysiptera*, which he proposed to call *T. Ellioti*. A communication was read from Mr. Harper Pease on the classification of the molluscs of the genus *Helicter*. A paper was read by Messrs. P. L. Sclater and O. Salvin on birds collected by Mr. W. H. Hudson at Conchitas, near Buenos Ayres, being their third communication to the Society upon this subject. Mr. Sclater exhibited and pointed out the characters of two new species of birds of the sub-family *Synallaxinæ*, proposed to be called *Synallaxis curtata* and *Leptasthenura andicola*. A communication was read from Capt. G. E. Bulger, entitled Notes on Two Animals observed near Wind-Vogel-berg, South Africa. Mr. R. Swinhoe, F.Z.S., read a paper on the Cervine Animals of the Island of Hainan, Southern China, which he stated to be referable to three species, namely:—*Cervulus vaginalis*, *Cervus* (*Panolia*) *Eldi*, and a Rusine Deer allied to *Cervus hippelaphus*. A communication was read from Mr. W. T. Blanford on the species of *Hyrax* inhabiting Abyssinia and the neighbouring countries, which he believed to be four in number. Dr. J. E. Gray communicated the description of a new species of *Emys*, living in the Society's Gardens, which he proposed to call *E. flavipes*, from an unknown locality.

Mathematical Society, December 9.—Professor Cayley, president, in the chair. Professor H. J. S. Smith communicated a note on the Focal Properties of two Correlative Figures. This paper was an appendix to a former paper by the same author, on the Focal Properties of Homographic Figures. By the term "focal properties" are intended those properties which arise from considering the imaginary circular points at an infinite distance in either figure, and the points corresponding to them in the other figure. These properties appear to be much less varied in their character in the case of two correlative figures than in the case of two homographic figures; and the two following theorems (of which the first is well known) will suffice to give an idea of the general nature of the results:—1. In two correlative figures in space there are always two corresponding tetrahedra, such that three adjacent edges of each are rectangular; the three edges opposite to these being at an infinite distance, and the edges at a finite distance in either figure corresponding to the edges at an infinite distance in the other. 2. If we consider any point in either figure, and its correlative plane in the other, we have two definite planes passing through the point, and two corresponding points upon the plane, which may be called respectively the cyclic planes of the point and the foci of the plane. If we take any third point in the plane, the angles which its focal radii vectores make with the line joining the foci are equal to the angles which the traces of the corresponding planes upon the cyclic planes make with the line of intersection of those two planes. These theorems suppose only that in the two correlative figures the plane at an infinite distance in either figure answers to a point at a finite distance in the other. Mr. Tucker (Hon. Sec.) read a proof (by Mr. M. W. Crofton, F.R.S.) of Gauss' Theorems and Napier's Analogies. The proof, a purely geometrical one, was extremely neat and simple. The perpendicular bisector of the base is produced to meet the external bisector of the vertical angle, and from the point of intersection (P) arcs are drawn perpendicular to the sides containing the said vertical angle. This point (P) is also connected by arcs with the extremities of the base; the results readily follow from the equality of certain triangles.—Mr. S. Roberts, M.A., gave an account of a short paper On the Order of the Discriminant of a Ternary Form. The main theorems, the author states, have been geometrically obtained by, and are due to, Professor Cremona (Mr. Roberts' paper contains an analytical proof of them), and relate to the influence of common multiple points on the number of double points of a pencil or involution of curves. The method employed was applied to the determination of the discriminant of a ternary form when certain of the terms are wanting, viz. the form (x, y) P(x, z)1. The communication also had reference to a paper on Discriminants, by Dr. Henrici, published in the Society's Proceedings, in which the result had been arrived at *indirectly*, and Mr. Roberts' aim was to clear up an apparent discrepancy in the results obtained by Professor Cremona and Dr. Henrici. The latter gentleman joined in a discussion on the subject.—The President gave an account of his investigations on the cen ro-surface of an ellipsoid (locus of the centres of curvature of the ellipsoid). The surface has been studied by Dr. Salmon, and also by Professor Clebsch, but in particular the theory of the nodal curve on the surface admits of further development. The principal sections of the surface (as is known) consist each of them of an ellipse counting three times, and of an evolute of an ellipse: the evolute and ellipse have four contacts (twofold intersections) and four simple intersections, but the contacts and intersections respectively are in the different sections real or imaginary. The form of the principal sections then is: a real contact at P in the plane of xz, and a real intersection at Q in the plane of xy; and thus there are an exterior and an interior sheet, but (instead of meeting in a conical point, as in the wave surface) these intersect in a nodal curve QP. The curve has a cusp at Q, and a node at P, thus extending beyond P, but from that point is acnodal, or without any real branch of the surface passing through it. Several simple relations were established, but the reductions were of some complexity.

Syro-Egyptian Society, December 7th.—W. H. Black, Esq. in the chair. Mr. Bonomi read a paper on the defacement of the name and figure of the god Amon on all Egyptian temples, obelisks, and statues, during the reign of the successor of Amnnohph III., and the subsequent restoration of both during the reign of Rameses II. Mr. Bonomi conjectures that the amount of skilled labour and expenses of scaffolding necessary to effect these changes prove that they were considered of great importance in a religious point of view; and he stated that there was scarcely a public or private collection of Egyptian antiquities in Europe that could not furnish examples of it. The beautiful drawings and photographs exhibited by Mr. Bonomi, to illustrate the subject, enhanced the interest of his able paper.

Institution of Civil Engineers, December 14.—Mr. Chas. Hutton Gregory, president, in the chair. The paper on Ocean Steam Navigation, with a view to its future development, by Mr John Grantham, M. Inst. C.E., partly read at the meeting on the 7th inst., was concluded; and a brief abstract of the whole is now given. The author contended that steam-ships could be employed more extensively on routes partially occupied by them, and on others where regular steam-lines had not yet been established. Rapid and regular voyages both for passengers and goods were now fully appreciated, while the greatly-increasing intercourse of all nations furnished freights which would support lines of expensive steam-vessels. He traced the rise of ocean steam navigation, and showed that the route from Liverpool to New York was the principal field on which it was first fully developed. He described the efforts made by the Americans to maintain by steam the prestige so long secured by their sailing ships; gave the reason for the great change that had taken place; and stated that not one American steamer was now running between Europe and America. Some of the causes of this were to be found in the fact, that iron ships, worked by the screw propeller, could alone be employed successfully, and that such ships in America were too expensive, both in their construction and in their working, to enable them to compete with English vessels. The form of, and various improvements in, the boilers and the engines were described, showing that a much higher pressure of steam was now employed, that the expansive system and surface condensation were at present considered essential to success in economising fuel, and that the amount of coals consumed had in the best vessels been reduced to 2¼lb. per indicated horse-power per hour, but it was anticipated that a reduction to 2lb. might soon be attained. A map on Mercator's projection was exhibited, indicating the principal ocean routes in connection with the trades between Great Britain and the rest of the world; and the improved system by great circle sailing, as recommended by Mr. Towson, of Liverpool, was described. A table was also exhibited of the relative distances between London and Liverpool, and the various ports shown on the map, both by long sea, and by the Suez Canal and the Pacific Railroad; from which it appeared that, as regarded the Northern Hemisphere, a great saving of distance and time would be effected. The number of ocean steam-ships now working in connection with this country was stated to be 364. The performances of the best ships of various companies were then alluded to, and the result showed that on the North American lines the highest average rate of speed was maintained, but by a large expenditure of fuel; that the Pacific and Colonial Companies' ships gave excellent results, as regarded economy of fuel; and that some new vessels, lately built for the Royal West India Mail Company, seemed to promise the best performances with respect to speed and economy combined. A table taken from the Board of Trade Returns for 1868 showed that, with North America, the tonnage of steam-ships nearly equalled that of sailing ships; but in the Mediterranean trade steam-ships largely exceeded sailing ships. On the other hand, in the regular trades with India, China, and Australia, steam tonnage, by long sea, comprised only about 1 per cent. of the whole. A calculation was then made to show what might be expected if the trade with the East was in future carried through the Suez Canal, and of the number of large steam-fleets which would be required to work it. Some facts were also recorded relative to the effect of the Pacific Railroad, and the probability of letters and passengers from China, Japan, and Western Australia going by that route. It was shown that several days' saving in time would be effected. The author considered that the voyage to Melbourne could be best performed by long sea, as there would be no saving either in distance or in time by way of Suez. The paper held out great prospects of advantage to England and to British shipbuilders, from the immense changes that were apparently about to take place.

Anthropological Society, December 14.—Dr. Charnock, V.P., in the chair. Mr. Wake read a paper on the Race Affinities of the Madecasses. The agreement of the *Hovas* with the other inhabitants of Madagascar in language and customs forbids us to refer the former to a Malayan origin. Moreover, the division into dark and light tribes is found in the Malayan Archipelago, and also in South Africa. Comparison of physical and mental characters, and of customs and superstitions, shows that the dark Madecasses, the Kafirs, and the Papuans, all belong to the same race. By a similar comparison, an analogous affinity between the Hovas, the Hottentots, and the Malays (as representative of whom the paper took the Siamese), can be established. The South African relationship of the Madecasses is supported by the verbal and grammatical affinity of the Malagasy to the Kafir and Hottentot dialects, which are shown to be related between themselves, and also to the Polynesian dialects. The arrangement of peoples on the African area is opposed to the idea of a continental origin of the Madecasses, while their numerous African affinities prevent their being traced to a Malayan source. The Madecasses are more really *autochthonous* than any other race except the aborigines of Australia, and probably Madagascar was connected with both the African Continent and the Malay Archipelago when it was first inhabited by man. The inhabitants of Madagascar possess the domestic ox, sheep, and fowl, and are skilled in the smelting and working of iron. This island was probably (according to the author) the seat of man's primitive civilisation.

DUBLIN

Royal Irish Academy, December 13.—The Rev. Professor Jellett, president, in the chair. Professor Sullivan, Ph.D., read a paper on the Beds of Thenardite of the Valley of Jarama, in connection with climatal effects supposed to be due to the variation of the eecentricity of the earth's orbit, according to the calculations of Messrs. Croll and Moore. The author remarked that M. Adhémar endeavoured to account for change of climate in geological time by the precession of the equinoxes, and the change of position of perihelion. These effects are modified by another astronomical movement—the change in the eccentricity of the earth's orbit. At the instance of Sir C. Lyell, Mr. Stone made some calculations to determine the eccentricity of the orbit in former periods, which Mr. Croll, by the aid of Leverrier's formula, has completed for one million years before 1800 in parts of a unit equal to the mean distance of the earth from the sun. These calculations are given by Sir C. Lyell in the last edition of his "Geology," with the addition of some calculations made by Mr. John Carrick Moore, of the mean temperature of the hottest and coldest months in the latitude of London, supposing other causes which may influence the distribution of heat to remain the same as at present. According to these tables, several periods of extreme temperature should have occurred within the million of years. The most marked of them should occur at 200,000, 210,000, and 750,000 years before 1800, when the mean temperature of the hottest month should be 113° Fahr., and of the coldest 1°·9, 0°·7, and 0°·6 respectively. Professor Tyndall has well pointed out that glaciers require heat as well as cold to produce them, so that extreme temperatures appear to represent the conditions required. These views appear to receive an unexpected support from a phenomenon which, being purely physical, gives more definite results than can in general be obtained from biological ones. In the Valley of the Jarama, a branch of the Tagus which receives the waters of the Manzanares, which flows through Madrid, occurs a series of beds,—thenardite, glauberite, gypsum, and clay,—having a variable thickness of from 16 to 19 metres. Through this the alluvial plain of the river has been cut. The formation of anhydrous sulphate of soda requires that the solution from which the salt separates should be above 35° Cent. or 95° Fahr. This is a temperature which even a shallow lake could only attain if the temperature of the air were considerably above that point. On the other hand, the conditions under which the sulphate of soda could be formed in the first instance requires a low temperature. So that, like glaciers, these beds require great heat and cold, the limits of which are, however, fixed in this case. If the temperature of the hottest month in the latitude of London were 113°, it would be still higher on the plain of Madrid, where even 120° Fahr. in the shade is sometimes even now attained in the locality of these beds. The circumstance which should exist at either of the glacial periods indicated by Mr. Croll's and Mr. Carrick Moore's calculations, would be sufficient to account for those beds; it would be difficult to account for them on the supposition of a period of intense cold. These beds were fully described in a paper by Professors Sullivan and O'Reilly, published in 1863 in Vol. iv. of the *Atlantis*, and afterwards in "Notes on the Geology and Mineralogy of the Spanish Provinces of Santander and Madrid." (London: Williams and Norgate. 1863.) Professors Apjohn and Hennessy took part in the discussion of the paper. J. R. Garstin, A.M., was elected a member of council in the room of Professor Jellett.

PARIS

Academy of Sciences, December 13.—M. H. Sainte-Claire Deville brought under the notice of the Academy a siderostat constructed by the late M. Léon Foucault, and communicated a note upon it by M. C. Wolf. Its action depends upon the production of a perfectly plane mirror, the mode of obtaining which was described in a posthumous paper by M. Léon Foucault, read to the Academy at a recent meeting (see NATURE, p. 177), and its object is to furnish the observer with a perfectly reflected image of any sidereal body for examination by the telescope. A figure of the instrument, which is provided with a clockwork movement, is given in illustration of M. Wolf's note.—M. Laugier remarked upon the employment of the plane mirror, and noticed that Arago had called attention twenty years ago to the advantages which might be derived from it. M. P. A. Favre presented some remarks upon the electric explorer described by M. Trouvé (see NATURE, p. 177), for the detection of metallic substances in wounds, and claimed for himself the invention, in 1862, of an electrical sound for the same purpose.—Marshal Vaillant announced that M. Pasteur was engaged at Trieste in completing a work upon sericulture, and in organising a silk-worm cultivation on a large scale, to be carried on in accordance with his system.—M. Haton de la Goupillière presented a memoir on the system of metallic floodgates which require the minimum of attraction.—A memoir on the dispersion of light, by M. M. Ricour, was communicated by M. Combes. General Morin presented a note by M. H. Morton, on the origin of the luminous band which is observed in contact with the margin of the moon's disc in the photographic pictures of various eclipses. In preparing negative photographs of eclipses, a slight band surrounds the border of the moon's shadow, in which the deposit of silver is more dense than elsewhere, producing a light band in that positive. The author has produced a similar effect by substituting a disc of dark paper for the moon's shadow, and he comes to the conclusion that the phenomenon is simply chemical, and due to the extension, during the development of the plate, of the nitrate of silver from the part protected by the shadow, to a short distance beyond the latter.—A note by M. Hugo Schiff, on the constitution of amygdaline and phloridzine, was communicated by M. Wurtz. The author describes and formulates these substances and their derivatives.—M. E. J. Maumené communicated another memoir on inverted sugar, in reply to M. Dubrunfant, in which he states that none of the latter's assertions are in accordance with experiment. He says that inverted sugar, properly prepared, is a mixture of three optically neutral bodies, which are neither glucose, nor levulose, nor any of the sugars possessing a rotatory power. The fermentation of inverted sugar is accompanied by no elective phenomena.—M. Dubrunfant presented a communication on spectrum analysis applied to the investigation of simple gases, and of their mixtures, in which he described the phenomena presented by various gases and gaseous mixtures under different conditions of pressure, and indicated that the supposed multiple spectra of certain gases are probably due to admixture. Thus it appears to be impossible to obtain hydrogen free from nitrogen, and under a low pressure the spectrum of the latter alone appears.—M. Jos. Boussingault communicated an analysis of the "morallon" emeralds from the mines of Muso, in New Granada.—A memoir was presented by M. Martin de Brettes on the determination of one or more of the following quantities, the others being given: The diameter of an oblong projectile, its weight, its initial velocity, the curve of its trajectory, and the weight of the gun from which it is fired. He gives the formulæ for working out these questions, and indicates their applications to artillery and small arms.—Of two zoological papers, one, by M. Lacaze Duthiers, calls the attention of naturalists to the Harbour of Roscoff, on the north coast of France, as a locality where the so-called *Pentacrinus europæus*, the young form of *Antedon rosaceus*, is to be found in abundance. From his description, the Bay of Roscoff is a paradise for the student of marine zoology.—The second memoir, by M. F. Lenormant, discusses the question of the antiquity of the ass and the horse as domestic animals in Syria and Egypt; and the author states, in opposition to Professor Owen, that the ass is represented very frequently upon the earliest known monuments. The horse, on the contrary, remained unknown in the countries south-west of the Euphrates until the time of the shepherd kings, or about the nineteenth century B.C. M. Milne-Edwards remarked upon this communication that it agreed with the conclusions of zoologists as to the distribution of the species of the genus *Equus*; the ass is to be regarded as an essentially African species, whilst the horse is a native of central Asia and part of Europe. He added that if the shepherd peoples introduced the horse into Egypt, this might throw some light upon their origin. M. Elie de Beaumont remarked that these facts were favourable to the opinion that the existing state of things on the surface of the globe was not of very ancient date.—M. J. Reboux communicated the results of some Prehistoric Archæological researches upon the quarternary beds of Paris, in which he indicated the character of numerous worked flints obtained by him from these beds (from a depth of twelve metres upwards), and gave a long list of animals, the remains of which were found intermixed with the flints.—M. Guérin-Méneville remarked upon the conditions of production of truffles.—A note was presented from M. Namias, describing his employment of hydrate of chloral with beneficial effects at the Hospital of Venice; and another from M. Thuau on a process for the instantaneous lighting and extinction of gas-lamps by means of electricity.

BRUSSELS

Royal Academy of Sciences, November 6.—Various meteorological reports were presented to the Academy, namely: On the Aurora Borealis of the 6th of October, 1869, by MM. A. Quételet and F. Terby; and on storms observed in various parts of Belgium, by MM. A. Quételet, Brauch, Malaise, Dewalque, and Leclercq, the last giving an account of the storm phenomena of the neighbourhood of Liége for the year 1869.—M. C. Montigny communicated a note on the phenomena of coloration of the edges of the sun's disc when near the horizon, in which he referred especially to the appearance of rose-coloured undulations upon the blue arch of the upper margin of the sun, remarked upon certain facts which seem to indicate that these are not produced by atmospheric dispersion or interference, and suggested that they may be due to the protuberances of the chromosphere.—M. E. Morren presented a paper on the contagion of the variegation of plants by means of grafting, both from the stock to the graft, and from the graft to the stock. His observations relate to *Abutilon Thompsoni*, and other species of the same genus.—A note on the wax of straw, by Dr. B. Radziszewski, was communicated by M. L. Henry. This substance, which is analogous to the wax obtained from the sugar-cane, was first observed in a paper-factory at Willebroeck; it is solid, white, insoluble in water, soluble in alcohol and ether, and crystallises from its alcoholic solution in small nacreous scales.—An important memoir, by M. E. Van Beneden, on a new and very large species of *Gregarina* was read; to this we shall revert elsewhere.

BERLIN

German Chemical Society, December 11.—On this date there was a general meeting for the purpose of electing its officers for the year 1870. The following gentlemen were elected:—President: Professor Rammelaberg, with 34 votes against 25 given to Professor Baeyer. Vice-presidents: Professors Baeyer, Hoffmann, Magnus, and Rose. Secretaries and Vice-Secretaries: Dr. Eichermann, Dr. Martius, Dr. Oppenheim, and Dr. Wichelhaus. Treasurer: Mr. Scherinn. Librarian: Dr. Scheibler. Resident Committee: Professor Finkener, Dr. Jacobser, Dr. Kunheim, Dr. Schultzen, and Dr. Vogel. Non-resident Committee: Professors Illasiwetz of Vienna, Hoppe-Scyler of Tuebingen, Kékulé of Bonn, Wislicenus in Zurich, and Wagner in Wurtzburg. Obituary notices of the late honorary member, Professor Graham, and the late member Mr. Beyrick in Berlin, were then read by the President.

December 13.—The following papers were read:—Riebermann and Gräbe on Anturacene-monocarbonic Acid. Baeyer and Emmerling: Synthesis of Indole. Ascher: The Transformation of Angelic into Valerianic Acid. Hofmann and Gentz on Brominated Derivatives of Xylidine and on Dixylyle-guanidine or Meloxylidine. Hofmann on an Isomeric diphenylated Guanidine; and on Sulphocyanate of Xylyle. Hobreller on the Action of Sulphuret of Carbon on Sulphuretted Urea. Naumann: The Law of Avogadro considered as a consequence of the laws by which the movement of gases are regulated. Bel-Trederi on a Third Monochlorinated Phenelo-sulphurous Acid. Cossa on the Constitution of Native Carbonates. Thomsen on the Inaccuracy caused by the use of Favre and Silbermann's Mercury-calorimeter. Rathke on Molecular Combinations. Ladenburg on the Molecular Weight of certain Protoxides and Protochlorides. Fleury on the Action of Pentachloride of Phosphorus on Phenolic Ethers.

VIENNA

Imperial Academy of Sciences, December 2.—Professor Zepharovich presented a fourth instalment of his mineralogical communications, in which he referred to crystals of ullmanite and pyrite, and to the fine twin-crystals of sphene which were found in 1863 on the Rothenkopf. A telegram was communicated from M. Tempel announcing the discovery of a comet at Marseilles on the 27th November. This comet was, in consequence, observed at Vienna by Professor Weiss on the 29th November, and subsequently by Dr. Theodor Oppolzer, who communicated the elements of its orbit and its ephemeris up to the 6th January, 1870, deduced from the observations at Marseilles, Vienna, Leipzig, and Carlsruhe. A memoir entitled "Development of the tetratosymmetrical division of the hexagonal crystal-system, with remarks upon the occurrence of circular polarisation," by M. Aristides Brezina, was communicated by Professor Lang.—Professor von Hochstetter communicated a third paper on the earthquake-wave in the Pacific Ocean, in August 1868, containing observations made in Australia.—M. Schrauf presented the first part of his investigations of Labradorite, containing a description of the mineral and a microscopical examination of its enclosures, and an account of the phenomenon of avanturinisation as presented by it.

DUBLIN

Royal Dublin Society, December 20.—G. J. Stoney, A.M., F.R.S., in the chair. Mr. John Adair read a paper on the Acclimatisation of Plants as a help to the advance of civilisation. The author treated this interesting subject from a practical point of view, leaning rather to the possibility of plants being acclimatised—at least sufficiently so to bear the ordinary winter climate of this country. Dr. Moore, Professor E. Perceval Wright, and others, took part in the discussion of the paper. Mr. A. G. More exhibited from the museum of the society three fine specimens, probably the only three known, of the Blue Mountain Duck of Jamaica (*Pterodroma Caribbœa* Carte) also a large specimen of the Grey Seal (*Halichœrus griseus* Nils), which he had shot during the last summer on the coast of Galway. Dr. Emerson Reynolds exhibited a collection of flint arrowheads found in Ireland, and a photograph of a portion of the Giant's Causeway. He mentioned having obtained for the museum a series of the Causeway basaltic columns, consisting of a central column and six encircling ones.

[This abstract reached us too late to be inserted in its proper place.—ED.]

DIARY

THURSDAY, DECEMBER 23.

SOCIETY OF ANTIQUARIES, at 8.30.—Confessionals in the Middle Ages: Abbé Cochet.

THURSDAY, DECEMBER 30.

ROYAL INSTITUTION, at 3—Light: Prof. Tyndall, F.R.S. (Juvenile Lectures.)

BOOKS RECEIVED

ENGLISH.—Catechism of the Decimal, Albert, and Metric Systems: A.W. Bonn (published by the author).—Madam How and Lady Why: Rev. C. Kingsley (Bell and Daldy).—Reptiles and Birds: L. Figuier, edited and adapted by Parker Gillmore (Chapman and Hall).—The Sun: Amedée Guillemin, translated from the French by Dr. Phipson (Bentley).—The Snakes of Australia: Gerard Krefft (Sydney: T. Richards).—Meteorological and Magnetical Observations made at Flagstaff Observatory, Melbourne: Geo. Neumayer. (Through Trübner & Co.)

AMERICAN.—The Trapper's Guide: S. Newhouse.—The New West: Charles Loring Brace.—Agricultural, Qualitative, and Quantitative Analysis: G. C. Caldwell.—Sorghum and its Products: F. L. Stewart.—Elements of Astronomy: C. J. White.—Annual of Scientific Discovery: Dr. J. Knuland.—The Mines of the West: Rossiter W. Raymond.—Report on the Machinery and Processes of the Industrial Arts, &c., at the Paris Exposition of 1867: F. A. B. Barnard.—The Myths of the New World: Dr. Daniel G. Brinton. (Through Trübner and Co.)—An Abstract of Measurements and Examinations of the Solar Eclipse of August 7, 1869. Lecture Notes on Physics. The Total Eclipse of August 7, 1869: all by Prof. Alfred M. Mayer, Ph.D. (From the author.)

FOREIGN.—De la Fécondation Artificielle: Jules Gautar (published by the author).—De l'Abus des Boissons Alcooliques: L. F. E. Bergent.—Die Spectralanalyse: Dr. H. Schellen.—Rapport sur le Progrès de la Chimie Organique pure: L. Micé.—Dictionnaire Botanique: E. G. de St. Pierre.—Die Physiologie: Dr. J. W. Czermak.—Stellung des Menschen: Ludwig Büchner. (Through Williams and Norgate.)

CONTENTS

Printed by R. CLAY, SONS, & TAYLOR, at 7 and 8, Bread Street Hill, in the City of London, and published by MACMILLAN & Co., 63, Bleecker Street, New York.—THURSDAY, December 23, 1869.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH

No. 9] THURSDAY, DECEMBER 30, 1869 [PRICE FOURPENCE

Registered for Transmission Abroad]

MACMILLAN AND CO.'S PUBLICATIONS.

PROFESSOR ROSCOE'S "SPECTRUM ANALYSIS." Lectures delivered in 1868. With Appendices, Engravings, Maps, and Chromo-lithographs of the Spectra of the Chemical Elements and Heavenly Bodies. Royal 8vo. 21*s.*

FORCE and NATURE: ATTRACTION AND REPULSION. The Radical Principles of Energy graphically discussed in their Relation to Physical and Morphological Development. By C. F. WINSLOW, M.D. 8vo. 14*s.*

"Dr. Winslow's treatise is one which deserves thoughtful and conscientious study."—*Saturday Review.*

Second Edition.

Mr. WALLACE'S "MALAY ARCHIPELAGO:" The Land of the Orang-Utan and the Bird of Paradise. A Narrative of Travel, with Studies of Men and Nature. Two Vols. Crown 8vo. With Nine Maps and more than 50 Illustrations, 24*s.*

"A vivid picture of tropical life, which may be read with unflagging interest, and a sufficient account of his scientific conclusions to stimulate our appetite without wearying us by detail. In short, we may safely say that we have seldom read a more agreeable book of its kind."—*Saturday Review.*

SIR C. W. DILKE'S "GREATER BRITAIN." A Record of Travel in English-Speaking Countries (America, Australia, India) during 1866 and 1867. With Illustrations. Fifth Thousand. Crown 8vo. 6*s.*

The Times.—"Sir Charles Dilke's account of his tour in the West is delightful reading from first to last. Even when we differ from him, we are always ready to admit the industry of his research and the accuracy of his information, as well as his exceedingly clear way of stating his views. As a mere work of travel his book is exceedingly pleasant reading, and it gives one, in a comparatively small compass, an infinity of information of the sort one most cares to have. Above all, it is eminently suggestive, and what we should pronounce its highest merit is not so much the knowledge it communicates as the craving it excites for more."

Saturday Review.—"Sir Charles Dilke has written a book which is probably as well worth reading as any book of the same aims and character that ever was written. Its merits are, that it is written in a lively and agreeable style, that it implies a great deal of physical pluck, that no page of it fails to show an acute and highly intelligent observer, that it stimulates the imagination as well as the judgment of the reader, and that it is on perhaps the most interesting subject that can attract an Englishman who cares for his country."

A NARRATIVE OF A YEAR'S JOURNEY THROUGH CENTRAL AND EASTERN ARABIA, 1862-3. By WILLIAM GIFFORD PALGRAVE. Fifth and Cheaper Edition, with Map, Plans, and Portrait of Author. Crown 8vo. 6*s.*

BY SIR SAMUEL WHITE BAKER.

Eighth Thousand.

THE ALBERT N'YANZA GREAT BASIN OF THE NILE, AND EXPLORATION OF THE NILE SOURCES. New and Cheaper Edition, with Portraits, Maps, and Illustrations. Two Vols. crown 8vo. cloth gilt, 16*s.*

Sixth Thousand.

THE NILE TRIBUTARIES OF ABYSSINIA, AND THE SWORD HUNTERS OF THE HAMRAN ARABS. With Portraits, Maps, and Illustrations. Third Edition. 8vo. cloth gilt, 21*s.*

Daily News.—"Sir Samuel Baker has added a much-coveted laurel to many honours of British discovery—he has conquered the secret of the mysterious river."

THE BRITISH EXPEDITION TO ABYSSINIA. Compiled from Authentic Documents. By CAPTAIN H. M. HOZIER, late Assistant Military Secretary to Lord Napier of Magdala. 8vo 9*s.*

Civil Service Gazette.—"Captain Hozier's literary ability and professional experience have given us what will be regarded as the standard work on this interesting subject. . . . We do not know that we ever met with any historical sketch which was at once more lucid, concise, and comprehensive."

A HISTORY OF CHEMICAL THEORY, from the Age of Lavoisier to the Present Time. By AD. WURTZ. Translated by H. WATTS, F.R.S. Crown 8vo. 6*s.*

Pall Mall Gazette.—"The discourse, as a *résumé* of chemical theory and research, evinces singular luminousness and grasp. A few judicious notes are added by the translator."

MACMILLAN & CO., LONDON.

PELICAN LIFE ASSURANCE COMPANY,

Established in 1797,

70, LOMBARD STREET, CITY, and 57, CHARING CROSS, WESTMINSTER.

Directors.

John Coope Davis, Esq.	Sir John Lubbock, Bart. F.R.S.
Henry Farquhar, Esq.	John Stewart Oxley, Esq.
Charles Emanuel Goodhart, Esq.	Benjamin Shaw, Esq.
Jas. A. Gordon, Esq. M.D. F.R.S.	Marmaduke Wyvill, Jun. Esq.

FINANCIAL POSITION.

Total Amount Insured, with Bonus Additions . .		£3,007,431
Liability on the same at 3 per cent. Interest . .		846,712
Accumulated Funds		1,227,253
Annual Revenue from Premiums	£92,787	
" from Interest	57,163	
		149,950

The whole invested in Government, Real, and other first-class Securities, in addition to which the assured have the guarantee of a large and wealthy proprietary.

For Prospectuses and Forms of Proposal apply at the Offices as above, or to the Agents of the Company.

ROBERT TUCKER,
Secretary and Actuary.

NEW ELECTRIC LAMP.—Browning's New Large Automatic Electric Lamp. In this lamp both carbons are moved by the electricity of the battery employed (without the aid of clockwork); the light remains uniform in height, and more steady in action than any of the expensive regulators previously introduced. Price £8 8*s.* Illustrated circular for stamped envelope.

JOHN BROWNING, Optical and Physical Instrument Maker to the Royal Observatory, &c. &c., 111, Minories, E., London. Established 100 years.

SPECTRUM APPARATUS.—John BROWNING has great pleasure in introducing, to the notice of Lecturers and others, an economical set of apparatus for projecting the spectra of metals, or the absorption bands of liquids, on a screen. Illustrated catalogue of Spectroscopes sent for thirteen stamps.

JOHN BROWNING, Optical and Physical Instrument Maker to the Royal Observatory, &c., &c., 111, Minories. Prize Medal, 1862. Established 100 years.

SCHOOL OF CHEMISTRY,

20, *GREAT MARLBOROUGH STREET, LONDON, W.*

DIRECTED BY ARTHUR VACHER.

BRAGG'S VEGETABLE CHARCOAL or PURE CARBON BISCUITS, a nutritious, pleasant, and healthful diet, which has produced great benefit and positive relief to thousands of sufferers from indigestion, bile, acidity, foul breath, dyspepsia, heartburn, worms, &c. There is medical testimony to its beneficial effect in these complaints.—Sold in tins, 1*s.*, 2*s.*, 4*s.*, and 8*s.* each, by all chemists, and by the manufacturer, J. L. BRAGG, 14 (late 2), Wigmore Street, Cavendish Square.

OZONE.

BARTH'S Apparatus with pure Oxygen retained in its active state by compression is specific in all Diseases arising from impurity of blood. May be had on Hire with option of purchase from G. BARTH & CO., 26, Duke Street, Bloomsbury, W.C.

GEOLOGY AND CONCHOLOGY.

Collections of Marine, Land, and Freshwater Shells, Tertiary, Cretaceous, Oolite, Liassic, Carboniferous, and Silurian Fossils, accurately named.

Price from 7*s.* 6*d.* each series.

THOMAS D. RUSSELL,
BRITISH NATURAL HISTORY COLLECTIONS,
Whittington Club, Arundel Street, London, W.C.

Full Particulars and Catalogue Post-free.

THURSDAY, DECEMBER 30, 1869

A DEDUCTION FROM DARWIN'S THEORY

THERE is one important consequence deducible from Darwin's profound theory which has not yet been noticed so far as I am aware. The theory is capable under certain reasonable conditions of accounting for the fact that the highest forms of civilisation have appeared in temperate climates.

Although some apparent exceptions might be adduced, it is no doubt true that man displays his utmost vigour and perfection, both of mind and body, in the regions intermediate between extreme heat and extreme cold, allowance being made for the reduced temperature of elevated mountain districts. The explanations hitherto given of this fact are of a purely hypothetical and shallow character. It is said, for instance, that the prolific character of the tropical climate too easily furnishes man with subsistence, so that his powers are never properly called into action. On the other hand in the Arctic regions nature is too sterile and no exertions can lead to the accumulation of much wealth. This explanation obviously involves the gratuitous hypothesis that man has been created with powers exactly suited to be called forth by just that degree of difficulty experienced in a temperate climate. There are those even who maintain our peculiar British climate to be the very best possible, because it taxes our powers of endurance to the last point which they can bear, and thus calls forth the greatest amount of energy. But here again is the assumption that the British people and the British climate were specially created to suit each other.

The theory of natural selection, on the other hand, represents that great method by which infinitely numerous adaptations will always be produced throughout time. Whatever happens in this material world must happen in consequence of the properties originally impressed upon matter, and our notions of the wisdom embodied in the Creation must be infinitely raised when we understand, however imperfectly, its true method. The continual resort to special inventions and adaptations must surely be below the greatness of a Power which could so design and create matter from the first that it must go on thenceforth inventing and adapting forms of life without apparent limit, in pursuance of one uniform principle.

I conceive it to be the essential consequence of Darwin's views that no form of life is to be regarded as a fixed form; but that all living beings, including man, are in a continual process of adjustment to the conditions in which they live. If this be so, it will of necessity follow that the longer any race dwells in given circumstances, the more perfectly will it become adapted to those circumstances. A migratory race, on the contrary, will always be liable to enter climates unsuited to it, and less favourable to the development of the greatest amount of energy. Negroes can bear a tropical heat simply because the race has grown more accustomed to it than Europeans, who bring with them indeed a superior degree of energy and intellect, but soon sicken and fail to reproduce themselves in equal perfection.

The intellect of man renders him far more migratory than most other animals, and when we look over long periods of time we must regard him as in a constant state of oscillation between the equator and the borders of perpetual snow. It will of necessity follow that the race, as a whole, will be better adapted to a medium than to an extreme climate. Not only may the same race have passed alternately through colder and hotter climates, but it is obvious that the tribes which intermix and intermarry in temperate regions will have come, some from a hotter and some from a colder region. The amalgamated race will therefore be precisely adapted to a medium climate. The inhabitants of the Arctic regions, on the contrary, must have come entirely from a warmer climate, and those of a tropical region from a colder climate, so that ages must pass before either re-adapts itself perfectly to its new circumstances.

It is hardly to be expected that history can afford complete corroboration of this theory; but I do not think that historical facts can be adduced in serious opposition to it. The progress of archæological and linguistic inquiry shows more and more clearly that the civilised parts of the earth have been inhabited by a succession of different races. A really aboriginal and indigenous people, growing upon a single island or spot of ground without kinship with other races, is not known to exist; and it is almost certain that all races have descended from a few stocks, if not from a single one. The evidences of extensive and frequent migrations are thus most complete, even if we had not distinct historical facts concerning the rapid and extensive movements of the Goths, Huns, Moors, Scandinavians, and many other races.

If the historical evidence disagrees with the theory in any point, it is that the migrations from temperate to extreme climates greatly over-balance any opposite movement. It would hardly, perhaps, be too much to represent the temperate regions of the Old World as the birthplace of successive races, which have diverged and died away more or less rapidly in distant and extreme climates. But if such be the conclusion from historical periods, it would only indicate that the human race had already acquired, in prehistoric times, a constitution displaying its greatest vitality in temperate regions. There can be no doubt that, were the rest of the world uninhabited by man, a very inferior race, such as the negroes of tropical Africa, would gradually re-people it; but they cannot do so in the present state of things, because they come into conflict with races of superior intellect and energy.

I would add in conclusion that the utmost result of speculations of this kind, supposing them to be valid, would consist in establishing a *general tendency*, so that the probabilities will be in favour of a great display of civilisation occurring in temperate climates rather than elsewhere. I do not for a moment suppose that any common physical cause, such as soil, climate, mineral wealth, or geographical position, or any combination of such causes, can alone account for the rise and growth of civilisation in Assyria, Egypt, Greece, Italy, or England. Material resources are nothing without the mind which knows how to use them. No physiology of protoplasm, no science that yet has a name, or perhaps ever will have a name, can account for the evolution of intellect in all its endless developments. The vanity of the Comtists leads them to suppose that their philosophy can compass the bounds of existence and account for the evolution of history; but the scientific man remembers that however complicated the facts which he reduces under the grasp of his laws, yet beyond all doubt there remain other groups of facts of surpassing complication. Science may ever advance, but, like an improved telescope in the hands of an astronomer, it only discloses the unsuspected extent and difficulty of the phenomena yet unreduced to law.

W. STANLEY JEVONS

THE STATE TELEGRAPHS

OUR Government—always the last among European Governments to endow the nation with any benefit resulting from the advance of science—has at length awakened to the fact that the electric current is the scientific modern equivalent for the ancient post-boy, and we are to have a State Telegraph as we have a State Postal system.

As early as 1854, Mr. Thomas Allan, the electrician, published a paper entitled "Reasons for the Government Annexing an Electric Telegraph System to the General Post Office," in which he recommended the adoption of a shilling rate, for messages of twenty words, throughout the United Kingdom. This paper was published a second time in 1863. In 1856, Mr. Baines, an officer in the General Post Office, submitted to the Lords of the Treasury a plan for the annexation of the telegraphs, and a general charge of sixpence for messages of twenty words. In 1861, a memorandum by Mr. Ricardo, chairman of the Electric and International Telegraph Company, recommending the transfer of the telegraphs to the Government, was forwarded to the Chancellor of the Exchequer. Late in the year 1865 the proposition was again brought forward in the report of a committee appointed by the Edinburgh Chamber of Commerce "to consider the present condition of telegraphic communication in the United Kingdom, with a view to its improvement." In June 1866, Mr. Edwin Chadwick also forwarded a like scheme to the Chancellor of the Exchequer. The substance of all these papers was to the effect that the existing charges were too high, that the rapidity of transmission of messages was bad, that improvements are slow where they have to be made by competing companies fighting for high dividends, and that telegraphing in consequence was in a more backward state in the United Kingdom than in Switzerland and Belgium.

In September 1865, Mr. Scudamore was requested by the Postmaster-General to take the whole subject into consideration, and to report thereon. His first report was presented in July 1866, followed by a second in February 1868. These reports set forth that before December 1862 messages of twenty words were transmitted for fifteen pence to or from any part of Belgium, in which country the telegraphs are under the control of the State. At the end of 1862 the charge was reduced to tenpence, and in December 1865 the charge was still further reduced to fivepence. The hours of business in the telegraphic offices in Belgium are much the same as those adopted in England. The clerks have the power, which they use largely, of altering the wording of messages so as to make them read clearer, and to prevent mistakes—a plan which manifestly would not work in England, and which would lead to many legal and other difficulties. The result of the reductions in charges was, that in 1860 one telegram was transmitted in Belgium to every 218 letters passing through the post; in 1863, one message was transmitted to every 114 letters; and in 1866, the proportion was one telegram to every 37 letters. He also reported that the charge for the transmission of messages of twenty words between any two towns in Switzerland was tenpence. In 1860, one telegram was transmitted in Switzerland to every 84 letters; in 1863, one telegram to every 74 letters; and in 1866, one telegram to every 69 letters. In the United Kingdom the proportion of telegrams to letters was, in 1860, one to 296; in 1863, one to 197; and in 1866, one to 121. At the close of the year, the telegraphic systems of Belgium and Switzerland had been in operation about fifteen years, and the working expenses during that period had amounted in the case of Switzerland to about 68 per cent., and Belgium 62½ per cent. of the total revenue during the period. At the end of the year 1866, both Governments had a good surplus on hand from the telegraphic departments. The post offices of Switzerland and Belgium have less work than that of the United Kingdom, as shown by the following table, giving national statistics for the year 1865:—

Nation.	Number of Inland Telegrams.	Number of Inland Letters.
Belgium . . .	332,718	24,530,688
Switzerland . .	364,118	25,183,136
United Kingdom	4,662,687	706,057,667

From these figures, Mr. Scudamore concluded that the use of the telegraphs was in a more backward state in the United Kingdom than in Switzerland or Belgium; and he recommended their transference to the Government. One principal reason urged by him to prove that the Government could better afford to send messages at a lower rate than the companies was, that the post offices could spare for the use of the telegraph 12,000 offices rent-free, and a large staff of officials at present engaged, but not all of them fully employed throughout the whole of their hours of duty.

He therefore recommended the purchase of the telegraphs by the State. In August last an Act of Parliament was passed by the late Government sanctioning the plan, and authority was given to buy up the telegraphs by paying the companies £5,715,048 8*s.* 11*d.* (The odd elevenpence shows the extreme nicety of the calculation.) The Electric International Telegraph Company will receive £2,938,826 9*s.* 0*d.*; the British and Irish Magnetic, £1,243,536; Reuter's Telegram Company, Limited, £726,000; the Universal Private Telegraph Company, £184,421 10*s.*; the London and Provincial Telegraph Company, Limited, £60,000; and the United Kingdom Telegraph Company, Limited, £562,264 9*s.* 11*d.*

At the present time everything relating to the transfer of the telegraphs to the Government is in a transition state, very many of the arrangements not having as yet been completed. It is intended, if possible, to effect the transfer on the 1st of January next; but so much preliminary work remains to be done, that it is doubtful whether all will be ready by that date. A large room has been fitted up in the General Post Office, with telegraphic instruments, in order that the clerks on the premises may learn to work them; and "dummy" instruments for the use of learners have been sent to the post offices in the provinces. The apparatus for common use will be the Morse printing telegraph and the single needle instrument; a wise selection, for long experience has proved them to be the best to place in the hands of unscientific clerks. They are not very liable to get out of order, and are very certain in their indications.

The following are among the changes that will be gradually made, some of them, however, at so distant a date that even the preliminaries have not been arranged as yet. The nine large district post offices in London will be made central stations, and each one will be connected by wire with the subordinate offices in its district. The chief post office in each of the largest provincial towns will be made a central telegraphic station, and the chief provincial towns will be placed in direct communication with three of the largest central London offices, namely, those in the West Central, Western, and South-western districts, in addition to the chief office in the East Central district. Suborbinate offices will be opened throughout the kingdom at the money-order offices in all places having a population of 2,000 persons and upwards. Messages will be received at all post offices for transmission by hand in the ordinary way to stations in connection with the telegraphic lines; pillar boxes will be places of deposit for messages written on stamped paper; and, as a rule, all messages will have to be paid for in stamps. The charge for transmission of a message of twenty words from any one part of the United Kingdom to any other part will be one shilling; but when it has to be delivered at a considerable distance from the nearest terminal station, it will be forwarded from that station by post for a penny, or by special messenger at sixpence per mile. Facilities will be given for the transmission of money-orders by telegraph, and as soon as possible the charges for messages to foreign parts will be reduced. Such are the plans which will be carried out, some of which will be in a very forward state in a few weeks' time.

THE GOLD FIELDS OF VICTORIA

The Gold Fields and Mineral Districts of Victoria. By R. Brough Smyth. (Melbourne: J. Ferres; London: Trübner and Co.)

II.

ALTHOUGH large quantities of gold are obtained from the detrital accumulations which overlie the palæozoic rocks of Victoria, there can be no doubt that they have come originally from the decomposition and removal of the auriferous quartz veins by which these rocks are traversed. The gold is simply a part of the detritus, in the same way that the fragments of quartz, sandstone, and slate are. Each nugget and bit of gold is only a more or less water-worn pebble, its edges being, as a rule, less worn, and its size larger, the nearer it is found to its parent reef. Yet some writers have endeavoured to show that the nuggets really grow by a kind of accretion, each fragment of gold becoming larger by successive depositions of the metal held in solution in the water percolating through the gravels. Mr. Brough Smyth, in discussing these and other disputed questions, usually avoids the expression of any decided opinion of his own. He treats them very much as a judge treats the evidence at a trial, and he leaves the decision to the jurymen, his readers. Yet we can very commonly guess what his opinions are, though he may not expressly state them. He gives us a tolerably copious account of opinions which have been published relative to the origin of quartz veins, and among these a valuable series of notes and sections specially made for him by a mining engineer of repute in the colony. The whole of this subject is, he says, involved in obscurity; "and though it is not possible for any one who has given attention to it to attach equal weight to the several theories which have been proposed, he would do wrong rashly to dismiss any of them as altogether improbable." Perhaps a judicial summing-up of this kind was, in the circumstances, better than the keen advocacy of any one theory. What is of value to the engineer in the colony is, to know what has really been written about the veins; and this he can learn with ease and satisfaction from Mr. Smyth's pages.

Allusion was made, in the previous notice of this volume, to the excellence of the geological and mining sections. It is rare to meet with such sections, so clearly conceived, so tastefully drawn, and carrying with them such conviction of their truth. The plate illustrative of the Ballarat gold fields is quite a model of clearness and clever drawing. No colour is used, but the various rocks are sharply defined, while, by the kind of drawing given to each, the internal structure of the mass is felicitously rendered. In the way of illustrations, the book seems to have only one failing, but it is a serious one: there is no geological map of the colony. The map at the end does not supply the want. A little coloured sketch-map, giving a general outline of the distribution of the geological formations, would have been an invaluable addition to the book, and would have certainly been worth a whole chapter of description.

One of the most striking facts brought out by the data compiled by Mr. Smyth is the high geological antiquity of the present land-surface of Victoria, or, in other words, the immense period during which that surface has remained above the sea. The palæozoic strata form the framework out of which the contour of the land has been moulded. These strata have been curved and folded, thrown on end, inverted, fractured, and upheaved. But the surface outlines are not found to bear any close relation to the direction of the subterranean movements. "There is scarcely one range in the colony which is not due to denudation, and those following lines of upheaval have been so modified by the action of water, through countless ages, as to make it difficult to determine where and how the elevating forces have operated." The palæozoic rocks were carved out into systems of valleys by the descent of rain-water from the watersheds to the lower grounds. Along these valleys river-gravels were laid down. In later times many volcanoes broke out, and thick streams of basalt rolled into the valleys and buried the ancient river-courses. Thus, in many places, the surface and the drainage of wide areas were wholly changed. New streams began to flow and to excavate new channels, which often flowed across the trend of the older valleys lying buried beneath them. By slow degrees these later valleys sank deeper into the framework of the country, often cutting down through the older water-courses. Speaking of Gippsland, the author remarks that the streams "have scooped out deep valleys. The lofty hills have not been upheaved in isolated masses, but are the remains of formations which have been swept away by the slow action of water. If all the rock-formations could be restored and placed in the positions which they once occupied, Gippsland would be an immense nearly level plateau. As a familiar illustration, we may liken the mountains formed of palæozoic rocks to the humps of earth left by the navvy when he digs a cutting The grass on the surface of the hump shows what was once the height of the ground which has been removed; and the recent tertiary formations on the tops of the hills in Gippsland are evidence of the original height of the whole area. The rocks which once occupied the intervening spaces have been eroded by water; and the height of the hills above the valleys affords some hint as to the vertical extent which has been cut away." The author believes that Victorian surface-geology affords "an answer to those geologists who have urged that the greater amount of erosion everywhere has been effected by marine agency, and not by rivers, rains, and the wasting action of the atmosphere." And, indeed, no one can study the maps and sections in this volume without being convinced that the erosion of the present and of the old valley-system has been wholly a sub-aërial process.

Mining operations have done a good deal towards elucidating the older system of water-courses which were overflowed and buried beneath basalt. These water-courses or "leads," as the miners call them, contain richly auriferous "drifts," and they are accordingly explored and ransacked by shafts and adits. Thus, at Ballarat, the river Yarrowee must have had its course shifted considerably eastward by the overflow of basalt. Its old winding channel has been explored under the overlying basalt, and the channels of its tributary rivulets from the east have been followed under the bed of the present river.

From the shafts and the natural sections along the sides of the valleys, we learn that the volcanic phenomena continued to manifest themselves for a prolonged period. Showers of ashes and streams of basalt were thrown out at long intervals, during which gravel and sand were accumulated in the water-courses above the last erupted materials. Hence we now find sections where sheets of basalt alternate with stream-gravel and with layers of clay and ancient soil. As in Auvergne, the lapse of time which separated the oldest from the most recent volcanic rocks cannot but have been great. On the one hand, some of the basalt plateaux have been trenched by valleys several hundred feet deep, and fragments of the plateaux have been left isolated; on the other hand, there occur craters and cones of ash so fresh that not many centuries may have passed away since they ceased to be in eruption.

But the changes of level effected by the outpouring of volcanic rocks at the surface have not been the only causes at work in greatly modifying the drainage of the country. In comparing the water-courses with the quantity of water flowing in them, still more in examining the endless lines of water-course in which there is no water at all, we are forced to conclude that the rainfall must be much less now than it was in a very recent geological period. Over a large part of Victoria the ground is low and sandy; and there the streams which come down from the hills, after wandering hopelessly about among pools and scrub, disappear altogether, being partly evaporated and partly absorbed into the parched soil. Mr. Smyth mentions an interesting fact when he says that the old drainage system of the country can often be traced only by the vegetation. "The Murray pine, in the midst of small Eucalypti, marks distinctly the line of the ancient water-courses." "The beds of old lakes and tributary creeks can now be discovered in some places only by the timber which they bear." This general desiccation of the country points to some wide-spread geological cause. Possibly it may be due—in part at least—to a comparatively recent elevation of the northern part of Australia, whereby the northerly winds, having a broad belt of land to pass over, lose much of their moisture before they reach the high lands of Victoria and New South Wales. The want of an abundant and constant supply of water is in some parts of the colony a serious obstacle to improvement. In particular, it operates most prejudicially upon gold-mining: no pains ought to be spared, therefore, to prevent the destruction of timber, and to take every opportunity of planting it where it is likely to be of service.

In conclusion, the volume which Mr. Smyth has produced, though too bulky and too detailed for general readers, is a storehouse of information on the subject of which it treats, and will undoubtedly take its place as one of the standard works of reference for all that relates to the occurrence and the mining of gold. ARCH. GEIKIE

OLIVER'S INDIAN BOTANY

First Book of Indian Botany. By Daniel Oliver, F.R.S., F.L.S., Keeper of the Herbarium and Library of the Royal Gardens, Kew, and Professor of Botany in University College, London. With numerous Illustrations. Small 8vo. pp. xii. and 394. (London: Macmillan and Co. 1869.)

THE want of special works introductory to the study of the botany of the principal tropical and southern countries of the globe has long been felt. The medical man, the student, and the amateur resident or travelling in India and our principal colonies, find it hard work to keep up or get up their botany by introductions and class-books founded on British plants, whilst the schoolmaster would find himself very much abroad who should attempt to teach his pupils Australian Botany by Henfrey's or Balfour's Introductions, or by Oliver's Elements. Hence the need of a series of works devoted to the teaching of botany with a special reference to the wants of the sojourners in foreign parts, and illustrated by the common plants to be found therein. With the exception of the admirable text-books of American Botany, of Asa Gray, we know of no work of the nature indicated, illustrative of any extra-European Flora. There was, indeed, some talk a few years ago of a series of such works, embracing all departments of Natural History, being authorised by the local governments of India,—but nothing has come from that quarter: and much as we then regretted the supineness of the Indian authorities in the matter, we no longer do so; for India could assuredly never have produced a work of so high an order as that whose title stands at the head of this notice, for a better considered and better executed work of the kind it has never been our good fortune to meet with, and it at once places its author first in the rank of English writers of Botanical Class-books.

Professor Oliver states in the preface that his book is in substance his "Lessons on Elementary Botany," adapted for use in India: but we find that it is this and a great deal more; for after following that excellent model in the part that relates to the structure of plants and the functions of their organs, a larger portion of the book is taken up with concise descriptions of 116 principal natural orders of India, illustrated by a clear analysis of the parts of a very common Indian flower, insomuch that, if we were asked what is the best text-book for a student in this country who wishes to acquire more knowledge of botany than is needful for a mere pass examination, without at all setting aside

Vertical Section of flower of *Nelumbium*, showing the hypogynous stamen and carpels singly immersed in a turbinate receptacle

the former work just mentioned, we do not know any to which we could so conscientiously direct attention, as almost all the plants in question may be easily found in any good botanic garden. Attached to each of the descriptions is a schedule of the floral characters on Henslow's plan, and a brief sketch of the principal matters of interest, structural, physiological, and economic, to be observed in Indian plants of the order, whilst the greater part are further accompanied by beautiful and original drawings and diagrams by Fitch, which delineate the floral organs graphically and naturally. We may add, too, that the more advanced and inquiring student has his attention occasionally directed to matters on which additional information is desired; as, for example, in the genus Drosera, where our author writes: "Some species exhibit a low sensibility or irritability in the leaves, which curl upon particles placed on their glandular hairs. Is this the case with Indian species? and do they appear to discriminate between organic and inorganic matter offered to them?"

Or, again, in Campanulaceæ: "Two small flowered Campanulas of Northern India exhibit the curious phenomenon of dimorphic flowers. Besides the flowers of usual form, there are smaller ones about the size of coriander seeds, which never open, but which nevertheless mature abundant seed. The latter must necessarily be self-fertilised, while the flowers of ordinary form are often, if not always, crossed by the pollen of other flowers of the same species. The part which these hermetically-sealed flowers play in the economy of plants is not yet well made out. They are found in isolated species and genera belonging to widely different natural orders, and it would be worth while to look for fresh examples amongst Indian weeds."

We consider such suggestions of extreme importance, as some stimulus of this kind is wanted to urge students to something more than the requirements of the passing time. It is notorious that though great acuteness is often shown amongst the higher proficients in botany who come before public examiners, not one in a hundred goes a step beyond what is wanted to secure a certain class or scholarship. There must, we imagine, be something in the style of public teaching on such subjects which seems to check all real interest, much less to excite a spirit of love or enthusiasm for science itself, without which it is quite certain that we shall have no new fellow-workers.

Sacred Lotus (*Nelumbium speciosum*), about one-tenth to one-fifteenth natural size

In conclusion, we would recommend a close study of the precision of our author's descriptions, and the clearness and terseness of his diction, to the writers of botanical text-books, as worthy of their imitation. These are qualities which improve the mind of the pupil more

Screw Pine (*Pandanus*), showing aërial adventitious roots than is usually supposed. They are conspicuously present in French class-books, but their absence is too often as conspicuous in English ones.

The author states in his preface that his chief difficulty has been in the selection of suitable plants to illustrate the natural orders, especially as types which are common in some parts of India, are absent in others. We think, however, that he has been extremely judicious in his selection, which certainly required no little local knowledge, and he has very properly recorded his obligations in this respect to our two great authorities on Indian botany, Dr. Hooker and Dr. Thomson.

If we were required to point out the especial part of the volume in which we think the author's tact has been more peculiarly developed, we would instance that in which he might be supposed to be least familiar. We have read with pleasure the observations on the cryptogamic orders, in admiration of the immense mass of information which is condensed within a short compass, and of its intrinsic value. We are glad to observe that some definitions are to be found in the very copious index, which did not come within the author's views in the text, and it would add greatly to their value if in a future edition little illustrations of such matters could be added in the margin. We have selected some woodcuts which are fair specimens of the 240 engravings in the book.

M. J. BERKELEY

OUR BOOK SHELF

Literature of Natural History.—*Bericht über die wissenschaftlichen Leistungen in der Naturgeschichte der niederen Thiere während der Jahre* 1866 *und* 1867. Von Dr. Rudolph Leuckart. (Berlin, 1869. London: Williams and Norgate.)

NOW that original observers in every branch of natural history are to be found in all civilised countries, it is only by means of such reports as this that the working naturalist can keep himself acquainted with the actual state even of that department of his science which he himself more particularly cultivates. When, as in the present case, a man of real eminence as a naturalist has at his command all the chief languages of Europe, and gives us year by year no mere dry list of papers but full analyses accompanied by critical remarks, we feel that it is not easy to exaggerate the importance of his labours as affecting the general progress of zoology. For the sake of any worker who may be unacquainted with Prof. Leuckart's reports, we may mention that they embrace the groups Vermes, Echinodermata, Cœlenterata, and Protozoa, as defined by German writers. The Rotiferi and Bryozoa are included under the Vermes.

Parsons on the Rose. *A Treatise on the Propagation, Culture, and History of the Rose.* By Samuel B. Parsons. Pp. 215. Illustrated. (New York. London: Trübner and Co.)

THE horticultural portion of this work, occupying its first nine chapters, is a digest of some of our best English authors on the subject. Chapter IX., on the Diseases and Insects attacking the Rose, is confessedly little more than a reproduction of the writings of Harris on the same topic, and of use *only* to the American cultivator.

The historical part, contained in Chapters X. to XV., exhibits a remarkable collation of gleanings from history—ancient, mediæval, or modern—of legends, fables, ceremonies, &c., all having some connection (although in some instances rather remote) with the rose. R. C. K.

The Romance of Natural History. By Philip Henry Gosse, F.R.S. 1st and 2d series. (London: James Nisbet and Co.)

THE popularity of these well-known volumes may be looked upon as a standing protest against the common opinion that the exact study of natural objects is inimical to a poetic conception and romantic love of nature. We know of no more delightful New Year's gift for an intelligent boy than Dr. Gosse's eloquent and well-illustrated work.

Our Dumb Neighbours; or, Conversations of a Father with his Children on Domestic and other Animals. By the Rev. T. Jackson. (London: S. W. Partridge and Co.)

THIS is a first-rate picture-book of animals for children. The text is not up to the level of the woodcuts.

Gedächtnisrede auf Alexander von Humboldt. Von H. W. Dove. (Berlin: Harrwitz und Gossman, 1869.)

Alexander von Humboldt. Festrede von Dr. A. Bastian. (Berlin: Wiegandt and Hemfel, 1869.)

THESE are addresses delivered, on the occasion of the recent Humboldt Centenary, before the Prussian Academy of Sciences, and the joint meeting of the scientific societies of Berlin. The memoir of Professor Dove records many interesting personal characteristics of the great German *savant*.

Monthly Bulletin of the Imperial Society of Acclimatation Second Series, January to November 1869.

THE Acclimatation (or, as we term it, Acclimatisation) Society of Paris, was founded in 1854, and appears to be in a most flourishing and active condition. The beautiful gardens of the society in the Bois de Boulogne are known to every visitor of Paris; but the work done by the society can be best judged of by glancing at its "Bulletins." An important part of the operations of the society consists in the distribution of animals and plants to its members, who may wish to experiment in endeavouring to acclimatise such useful species as the society may obtain. Pisciculture of all kinds, marine and fresh-water, occupies a large share of the attention of the society: ostreo-culture also and the coral-fisheries—which the French Government has most anxiously fostered on the coast of Algeria—are noticed in articles giving account of recent progress in these departments of industry. The cultivation of the silkworm, however, calls forth the most notable exertions of the society. Large districts in the south of France are given up to this employment. On some of the limestone plateaux north of Nimes—which are bare for miles and present no soil—holes are excavated, and the necessary earth in which to place the mulberry-trees which are to feed the crops of silkworms reared by the inhabitants of this district is fetched from thirty miles' distance—so valuable is the crop of silk when obtained. To these "Bulletins" we shall return as they make their monthly appearance. At present, on glancing through the year's accumulation, we find, amongst other facts of more than economical interest, an account of the introduction of the salmon of the Rhine into the Lake of Geneva. It has always been held doubtful as to whether salmon could thrive when access to the sea was impossible. The great length of the Rhone, and the overpowering force of its waters at the spot near Bellegarde, called *la perte du Rhône*, renders the Lake of Geneva practically closed from communication with the sea for all icthyological purposes. Hence it is exceedingly interesting to find that success has attended the efforts of Dr. Chavannes and others to introduce the Rhine salmon to this area. Specimens, put in among many thousand others in 1857, have been recaptured, weighing over four pounds, and with roe; whilst others, evidently the offspring of these, have been also taken. Further experiments are being made on an *actually* closed lake.

A PLEA FOR THE MATHEMATICIAN

[At the request of the Editor, Professor Sylvester has furnished the following abridgment of his opening address to the Mathematical and Physical Section of the British Association at Exeter, with some supplemental notes appended in the course of its passing through the press.—ED.]

I.

IT is said of a great party leader and orator in the House of Lords that, when lately requested to make a speech at some religious or charitable meeting, he declined to do so on the ground that he could not speak unless he saw an adversary before him—somebody to attack or reply to. In obedience to a somewhat similar combative instinct, I set to myself the task of considering certain recent utterances of a most distinguished member of this Association, one whom I no less respect for his honesty and public spirit than I admire him for his genius and eloquence, but from whose opinions on a subject which he has not studied I feel constrained to differ. Göthe has said—

> " Verständige Leute kannst du irren sehn
> In Sachen nämlich, die sie nicht verstehn."

Understanding people you may see erring—in those things, to wit, which they do not understand.

I have no doubt that had my distinguished friend, the probable President-elect of the next Meeting of the Association, applied his uncommon powers of reasoning, induction, comparison, observation, and invention to the study of mathematical science, he would have become as great a mathematician as he is now a biologist; indeed he has given public evidence of his ability to grapple with the practical side of certain mathematical questions; but he has not made a study of mathematical science as such: and the eminence of his position and the weight justly attaching to his name, render it only the more imperative that any assertions proceeding from such a quarter, which may appear to be erroneous, or so expressed as to be conducive to error, should not remain unchallenged or be passed over in silence.

He says "mathematical training is almost purely deductive. The mathematician starts with a few simple propositions, the proof of which is so obvious that they are called self-evident, and the rest of his work consists of subtle deductions from them. The teaching of languages, at any rate as ordinarily practised, is of the same general nature—authority and tradition furnish the data, and the mental operations are deductive." It would seem from this that, according to Prof. Huxley, the business of the mathematical student is from a limited number of propositions (bottled up and labelled ready for future use) to declare any required result by a process of the same general nature as a student of language employs in declining and conjugating his nouns and verbs: that to make out a mathematical proposition and to construe or parse a sentence are equivalent or identical mental operations. Such an opinion scarcely seems to need serious refutation. The passage is taken from an article in *Macmillan's Magazine* for June last, entitled "Scientific Education—Notes of an After-dinner Speech," and I cannot but think would have been couched in more guarded terms by my distinguished friend had his speech been made before dinner instead of after.

The notion that mathematical truth rests on the narrow basis of a limited number of elementary propositions, from which all others are to be derived by a process of logical inference and verbal deduction, has been stated still more strongly and explicitly by the same eminent writer in an article of even date with the preceding, in the *Fortnightly Review*, where we are told that "Mathematics is that study which knows nothing of observation, nothing of experiment, nothing of induction, nothing of causation." I think no statement could have been made more opposite to the facts of the case: that mathematical analysis is constantly invoking the aid of new principles, new ideas, and new methods, not capable of being defined by any form of words, but springing direct from the inherent powers and activity of the human mind, and from continually renewed introspection of that inner world of thought of which the phenomena are as varied and require as close attention to discern as those of the outer physical world—to which the inner one in each individual man may, I think, be conceived to stand in somewhat the same general relation of correspondence as a shadow to the object from which it is projected, or as the hollow palm of one hand to the close fist which it grasps of the other: that it is unceasingly calling forth the faculties of observation and comparison, that one of its principal weapons is induction, that it has frequent recourse to experimental trial and verification, and that it affords a boundless scope for the exercise of the highest efforts of imagination and invention.*

Lagrange, than whom no greater authority could be quoted, has expressed emphatically his belief in the importance to the mathematician of the faculty of observation :† Gauss has called mathematics a science of the

* The annexed instance of Mathematical Euristic is, I think, from its intrinsic interest, worthy of being put on record. The so-called canonical representation of a binary quartic of the eighth degree I found to be a quartic multiplied by itself, together with a sum of powers of its linear factors, just as for the fourth degree it was known to be a quadric into itself, together with a sum of powers of its factors: but for a sextic a cubic multiplied into itself, with a tail of powers as before, was not found to answer. To find the true representation was like looking out into universal space for a planet desiderated according to Bode's or any other empirical law. I found my *desideratum* as follows: I invented a catena of morphological processes which, applied to a quadric or to a quartic, causes each to reproduce itself: I then considered the two quadrics and two quartics to be noumenally distinguishable (one as an auto-morphic derivative of the other), although phenomenally identical. The same catena of processes applied to the cubic gave no longer an identical but a distinct derivative, and the product of the two I regarded as the analogue of the before-mentioned square of the quadric or of the quartic. This product of a cubic by its derivative so obtained together with a sum of powers of linear factors of the original cubic, I found by actual trial to my great satisfaction satisfied the conditions of canonicity, and it was thus I was led up to the desired representation which will be found reproduced in one of Prof. Cayley's memoirs on Quantics and in Dr. Salmon's lectures on Modern Algebra. Here certainly induction, observation, invention, and experimental verification all played their part in contributing to the solution of the problem. I discovered and developed the whole theory of canonical binary forms for odd degrees, and, as far as yet made out, for even degrees too, at one evening sitting, with a decanter of port wine to sustain nature's flagging energies, in a back office in Lincoln's-Inn-Fields. The work was done, and well done, but at the usual cost of racking thought—a brain on fire, and feet feeling, or feelingless, as if plunged in an ice pail. *That night we slept no more.* The canonisant of the quartic (its cubic covariant) was the first thing to offer itself in the inquiry. I had but to think the words "Resultant of Quintic and its Canonisant," and the octodecadic skew invariant would have fallen spontaneously into my lap. By quite another mode of consideration M. Hermite subsequently was led to the discovery of this, the key to the innermost sanctuary of Invariants—so hard is it in Euristic to see what lies immediately before one's eyes. The disappointment weighed deeply, far too deeply, on my mind, and caused me to relinquish for long years a cherished field of meditation: but the whirligig of time brings about its revenges. Ten years later this same canonisant gave me the upper hand of my honoured predecessor and guide, M. Hermite, in the inquiry (referred to at the end of this address) concerning the invariantive criteria of the constitution of a quintic with regard to the real and imaginary. By its aid I discovered the essential character of the famous amphigenous surface of the ninth order, and its bicuspidal universal section of the fourth order (otherwise termed the Bicorn), as may be seen in the third part of my Triology, printed in the Philosophical Transactions.

† I was under the conviction that a passage to that effect from Lagrange had been cited to me some years ago by M. Hermite of the Institute of France; on applying to him on the subject, I received the following reply:—

"Relativement à l'opinion que suivant vous j'aurais attribuée à Lagrange, je m'empresse de vous informer qu'il ne faut aucunement, à ma connaissance, l'en rendre responsable. Nous nous sommes entretenus du rôle de la *faculté d'observation dans les études que nous avons poursuivies de concert pendant bien des années*, et c'est alors, sans doute, que je vous aurai conté une anecdote que je tiens de M. Chevreul. M. Chevreul, allant à l'Institut dans la voiture de Lagrange, a été vivement frappé du sentiment de plaisir avec lequel ce grand géomètre lui faisait voir, dans un travail manuscrit, la beauté extérieure et artistique, si je peux dire, des nombreuses formules qui y figuraient. Ce sentiment nous l'avons tous éprouvé en faisant, avec sincérité, abstraction de l'idée analytique dont les formules sont l'expression écrite. Il y a là, n'est-il point vrai, un imperceptible lien qui rattache au monde de l'art le monde abstrait de l'algèbre et de l'analyse, et j'oserai même vous dire que je crois a des sympathies réelles, qui vous font trouver un charme, dans les notations d'un auteur, et dans les répulsions qui éloignent d'un autre, par l'apparence seule des formules."

I am, however, none the less persuaded that on one or more than one occasion, M. Hermite, speaking of Lagrange, expressed to me, if not as I supposed on Lagrange's, then certainly on his own high authority, "that the faculty of observation was no less necessary for the successful cultivation of the pure mathematical than of the natural sciences."

eye, and in conformity with this view always paid the most punctilious attention to preserve his text free from typographical errors: the ever to be lamented Riemann has written a thesis to show that the basis of our conception of space is purely empirical, and our knowledge of its laws the result of observation; that other kinds of space might be conceived to exist, subject to laws different from those which govern the actual space in which we are immersed; and that there is no evidence of these laws extending to the ultimate infinitesimal elements of which space is composed. Like his master Gauss, Riemann refuses to accept Kant's doctrine of space being a form of intuition,* and regards it as possessed of physical and objective reality. I may mention that Baron Sartorius von Waltershausen (a member of this Association), in his biography of Gauss ("Gauss zu gedächtniss"), published shortly after his death, relates that this great man was used to say that he had laid aside several questions which he had treated analytically, and hoped to apply to them geometrical methods in a future state of existence, when his conceptions of space should have become amplified and extended; for as we can conceive beings (like infinitely attenuated book-worms in an infinitely thin sheet of paper) which possess only the notion of space of two dimensions, so we may imagine beings capable of realising space of four or a greater number of dimensions.† Our Cayley, the central luminary, the Darwin of the English school of mathematicians, started and elaborated at an early age, and with happy consequences, the same bold hypothesis.

Most, if not all, of the great ideas of modern mathematics have had their origin in observation. Take, for instance, the arithmetical theory of forms, of which the foundation was laid in the diophantine theorems of Fermat, left without proof by their author, which resisted all the efforts of the myriad-minded Euler to reduce to demonstration, and only yielded up their cause of being when turned over in the blowpipe flame of Gauss's transcendent genius; or the doctrine of double periodicity, which resulted from the observation by Jacobi of a purely analytical fact of transformation; or Legendre's law of reciprocity; or Sturm's theorem about the roots of equations, which, as he informed me with his own lips, stared him in the face in the midst of some mechanical investigations connected (if my memory serves me right) with the motion of compound pendulums; or Huyghen's method of continued fractions, characterised by Lagrange as one of the principal discoveries of "that great mathematician, and to which he appears to have been led by the construction of his 'Planetary Automaton;'" or the new algebra, speaking of which one of my predecessors (Mr. Spottiswoode) has said, not without just reason and authority, from this chair, "that it reaches out and indissolubly connects itself each year with fresh branches of mathematics, that the theory of equations has almost become new through it, algebraic geometry transfigured in its light, that the calculus of variations, molecular physics, and mechanics" (he might, if speaking at the present moment, go on to add the theory of elasticity and the developments of the integral calculus) "have all felt its influence."

Now this gigantic outcome of modern analytical thought, itself, too, only the precursor and progenitor of a future still more heaven-reaching theory, which will comprise a complete study of the interoperation, the actions and reactions, of algebraic forms (Analytical Morphology in its absolute sense), how did this originate? In the accidental observation by Eisenstein, some twenty or more years ago, of a single invariant (the Quadrinvariant of a Binary Quartic) which he met with in the course of certain researches just as accidentally and unexpectedly as M. Du Chaillu might meet a Gorilla in the country of the Fantees, or any one of us in London a White Polar Bear escaped from the Zoological Gardens. Fortunately, he pounced down upon his prey and preserved it for the contemplation and study of future mathematicians. It occupies only part of a page in his collected posthumous works. This single result of observation (as well entitled to be so called as the discovery of Globigerinæ in chalk

* It is very common, not to say universal, with English writers, even such authorised ones as Whewell, Lewes, or Herbert Spencer, to refer to Kant's doctrine as affirming space "to be a form of thought," or "of the understanding." This is putting into Kant's mouth (as pointed out to me by Dr. C. M. Ingleby), words which he would have been the first to disclaim, and is as inaccurate a form of expression as to speak of "the plane of a sphere," meaning its surface or a superficial layer, as not long ago I heard a famous naturalist do at a meeting of the Royal Society. Whoever wishes to gain a notion of Kant's leading doctrines in a succinct form, weighty with thought, and free from all impertinent comment, should study Schwegler's Handbook of Philosophy, translated by Stirling. He will find in the same book a most lucid account of Aristotle's doctrine of matter and form, showing how matter passes unceasingly upwards into form, and form downwards into matter; which will remind many of the readers of NATURE of the chain of depolarisations and repolarisations which are supposed to explain the decomposition of water under galvanic action, eventuating in oxygen being thrown off at one pole and hydrogen at the other (it recalls also the high algebraical theories in which the same symbols play the part of operands to their antecedents and operators to their consequents): at one end of the Aristotelian chain comes out πρώτη ὕλη, at the other, πρῶτον εἶδος. We have, then, only to accept and apply the familiar mathematical principle of the two ends of infinity being one and the same point, and the otherwise immoveable stumblingblock of duality is done away with, and the universe reintegrated in the wished-for unity. For this corollary, which to many will appear fanciful, neither Aristotle nor Schwegler is responsible. We perfectly understand how in perspective the latent polarities of any point in a closed curve (taken as the object) may be developed into and displayed in the form of a duad of *quasi* points at an infinite distance from each other in the picture. In like manner we conceive how *actuality* and *potentiality* which exist indistinguishably as one in the *absolute* may be projected into seemingly separate elements or moments on the plane of the human understanding. Whatever may be the merits of the theory in itself, this view seems to me to give it a completeness which its author could not have anticipated, and to accomplish what Aristotle attempted but avowedly failed to effect, viz. the complete subversion of the "Platonic Duality," and the reintegration of matter and mind into one.

† It is well known to those who have gone into these views, that the laws of motion accepted as a fact suffice to prove in a general way that the space we live in is a flat or level space (a "homaloid"), our existence therein being assimilable to the life of the bookworm in a flat page: but what if the page should be undergoing a process of gradual bending into a curved form? Mr. W. K. Clifford has indulged in some remarkable speculations as to the possibility of our being able to infer, from certain unexplained phenomena of light and magnetism, the fact of our level space of three dimensions being in the act of undergoing in space of four dimensions (space as inconceivable to us as our space to the supposititious bookworm) a distortion analogous to the rumpling of the page. I know there are many, who, like my honoured and deeply lamented friend the late eminent Prof. Donkin, regard the alleged notion of generalised space as only a disguised form of algebraical formulisation; but the same might be said with equal truth of our notion of infinity in algebra, or of impossible lines, or lines making a zero angle in geometry, the utility of dealing with which as positive substantiated notions no one will be found to dispute. Dr. Salmon, in his extensions of Chasles' theory of characteristics to surfaces, Mr. Clifford, in a question of probability (published in the *Educational Times*), and myself in my theory of partitions, and also in my paper on Barycentric Projection in the *Philosophical Magazine*, have all felt and given evidence of the practical utility of handling space of four dimensions, as if it were conceivable space. Moreover, it should be borne in mind that every perspective representation of figured space of four dimensions is a figure in real space, and that the properties of figures admit of being studied to a great extent, if not completely, in their perspective representations. In philosophy, as in æsthetic, the highest knowledge comes by faith. I know (from personal experience of the fact) that Mr. Linnell can distinguish purple tints in clouds where my untutored eye and unpurged vision can perceive only confused grey. If an Aristotle, or Descartes, or Kant assures me that he recognises God in the conscience, I accuse my own blindness if I fail to see with him. If Gauss, Cayley, Riemann, Schalfli, Salmon, Clifford, Krönecker, have an inner assurance of the reality of transcendental space, I strive to bring my faculties of mental vision into accordance with theirs. The positive evidence in such cases is more worthy than the negative, and actuality is not cancelled or balanced by privation, as matter plus space is none the less matter. I acknowledge two separate sources of authority—the collective sense of mankind, and the illumination of privileged intellects. As a parallel case, I would ask whether it is by demonstrative processes that the doctrine of limits and of infinitely greats and smalls, has found its way to the ready acceptance of the multitude; or whether, after deducting whatever may be due to modified hereditary cerebral organisation, it is not a consequence rather of the insensible moulding of the ideas under the influence of language which has become permeated with the notions originating in the minds of a few great thinkers? I am assured that Germans even of the non-literary classes, such as ladies of fashion and novel readers, are often appalled by the habitude of their English friends in muddling up together, as if they were nearly or quite the same thing, the reason and the understanding in doing into English the words Vernunft and Verstand, thereby confounding distinctions now become familiar (such is the force of language) to the very milkmaids of Fatherland.

As a public teacher of mere striplings, I am often amazed by the facility and absence of resistance with which the principles of the infinitesimal calculus are accepted and assimilated by the present race of learners. When I was young, a boy of sixteen or seventeen who knew his infinitesimal calculus would have been almost pointed at in the streets as a prodigy, like Dante, as a man who had seen hell. Now-a-days, our Woolwich cadets at the same age talk with glee of asymptotes and points of contrary flexure, and discuss questions of double maxima and minima, or ballistic pendulums, or motion in a resisting medium, under the familiar and ignoble name of *sums*.

of of the Confoco-ellipsoidal structure of the shells of the Foraminifera), which remained infructuous in the hands of its distinguished author, has served to set in motion a train of thought and propagated an impulse which have led to a complete revolution in the whole aspect of modern analysis, and will continue to be felt until Mathematics are forgotten and British Associations meet no more.

J. J. SYLVESTER

TECHNICAL EDUCATION

MANCHESTER at all events is beginning to be alive to the present situation, and at a meeting on the 18th inst., the following document, expressing the views of the Council of the Society of Arts, was read.

1. The Council of the Society of Arts have received a communication from Owens College Extension Committee, Manchester, asking their co-operation in the extension of technical education, or, more properly, Scientific Instruction; and it affords them much pleasure to do whatever lies in their power to advance this important national object. With this view, the Council have invited the members of the Society, and especially those resident in the locality, as well as the authorities of Owens College, to meet them in conference on the subject, to discuss the best means by which scientific instruction may be promoted, and to establish an organisation which will keep an influence at work to accomplish what is so urgently needed.

2. The necessity and importance of improved scientific instruction for the people of the United Kingdom, in order that they may be placed in a favourable position in the race of industrial competition with other nations, has, for some time past, been forced upon the notice of the Society of Arts, whose chartered objects are the Promotion of Arts, Manufactures, and Commerce.

3. The great international displays of industry in 1851, 1855, 1862, and 1867, have shown unmistakeably that, if this country is to maintain her position as a commercial and manufacturing power, the people (and in this term are comprehended not only artisans, but also persons of higher position in the social scale) must have at their command the means of education improved in its general character, and embracing, if not based upon, science to a far greater extent than has hitherto been the case. The official jury reports at all the exhibitions abound in declarations of this character, and the country can no longer afford to ignore the fact, but must earnestly set to work to bring about a change. These reports, as well as those of the artisans who were sent to the Paris Exhibition of 1867 by the Society, one and all point out the great educational facilities which are available for all classes, and especially the artisan class, upon the Continent.

4. The Council are of opinion that existing schools and colleges, where science has hitherto been all but excluded, should adopt some means for its being taught; and that where such teaching already exists, measures should be taken for extending the usefulness of the institutions, and rendering them more easy of access to the great body of the people; whilst in localities where no such facilities exist, means should be taken to secure their foundation. The localities must themselves stir in this reform, and their efforts should be aided by pecuniary assistance and countenance by the State.

5. The nation must set itself earnestly to work to bring about the sought-for change in the education of the people. The evils have been so often pointed out, that it is unnecessary to enter into detail; our duty is to supply the remedy. This the Council believe to be by the localities setting themselves heartily to work, and when they have shown themselves in earnest by raising funds and organising establishments for the teaching of science, they should be entitled, as of right, to aid from the State.

6. In order, however, that such establishments, colleges, or schools should be of value to the mass of the people, so that they can take advantage of the facilities which would then be offered to them, it is absolutely necessary that elementary education, commonly known as primary education, should be extended far more widely than at present. To an ignorant population the establishment of colleges and schools for the teaching of science will be of little avail, and unless the blessings of an ordinary elementary education, *i.e.*, reading, writing, and arithmetic, at least, can be more diffused, so as to place our people on a par with those of Switzerland, Prussia, Saxony, &c., the attempt to extend the teaching of science will be in vain. Again, not only must we have improved elementary education, but these elements must themselves be taught by improved methods and organisation, so that less time may be occupied in acquiring them, thus leaving free for the learning of elementary science some of those years which are now unnecessarily taken up in mastering the mere rudiments of knowledge. Abroad it is the custom of the State only to deal with this and many other matters of public concern, but such is not the case here. The Council do not recommend State interference as of choice, but of necessity. This work of education must be done, and will have to be done, wholly by Government, if not otherwise. Experience proves that it can be done by a combination of voluntary efforts with Government aid, as in the existing system of primary education, and in the instruction aided by the Science and Art Department. The Council think that the work is to be done in part nationally, in part voluntarily, but not upon a haphazard system.

7. Adam Smith, the earliest, and, perhaps, the first English writer on political economy, as well as Mr. J. Stuart Mill, its present most able exponent, recommend scientific instruction as profitable to the nation. Her Majesty's Government must not plead economy as an excuse, for the highest and wisest economy comes out of wise expenditure.

8. The Council believe that this is the feeling of the country, which the Government will regard with respectful attention. Government must be urged to co-operate with Owens College and other bodies, either existing or to be established. Parliamentary grants are now made to the old universities of England and Scotland, and to the Queen's Colleges in Ireland, and there is no reason why the same principle should not be extended, and grants made to modern educational establishments in the great centres of industry. The Council are of opinion that a Government resulting from a wide representation of the whole people ought adequately to represent the highest intelligence and aspirations of that people for improvement, and not limit its responsibility and its labours to matters of police. There can be no more profitable investment of national capital drawn from taxes paid by the whole nation, than in promoting the best education among all classes of the people, and the widest extension of sound knowledge, on which the Arts, Manufactures, and Commerce of a kingdom rest.

At the meeting, the following resolution, proposed by Professor Jack, was carried unanimously:—

"That the best interests of the country demand the establishment of a complete system of primary education, the extension of the system of science classes under a responsible department of the Government, and under a definite plan, and especially the establishment of Science Colleges in the principal industrial centres of the United Kingdom: and such colleges ought to be established and maintained partly by local efforts, and partly by liberal assistance from the State; and existing institutions such as Owens College ought to be made available for the purpose."

For the present, we content ourselves with chronicling these facts, and calling upon other centres of industry, such as Birmingham, to help to bring the pressure of public opinion to bear upon the members of the Government, who, perhaps, more than anyone else, require to be taught the vital importance of technical education to the future national life.

WHENCE COME METEORITES?

IN examining a mass of meteoric iron found in the Cordillera of Deesa (Chili), M. Stanislas Meunier, of the Museum of Natural History in Paris, has discovered evidences of an unexpected relationship between this iron and two meteorites fallen at a great distance from Chili; viz. a mass of iron found at Caille (Alpes Maritimes), and a stone which fell at Sétif (Algeria) June 9, 1867.

The meteorite of Deesa is a mixture of these two rocks: it is composed of iron which is identical with that of Caille, injected in a state of fusion into a stone which is identical with that of Sétif. The iron of Deesa is thus evidently an eruptive rock, and it is the first hitherto observed among meteorites. Besides this, it is asserted that the iron resembling that found at Caille, and the stone resembling that of Sétif, have been mutually connected by stratification upon an unknown globe, and it is the first time that such a connection has been materially demonstrated.

M. Meunier remarks that the meteorites which now arrive upon the earth are not of the same mineralogical nature as those which fell in past ages. Formerly iron fell; now stones fall. During the last 118 years there have been in Europe but three falls of iron, whereas there have been, annually, on an average, three falls of stones. The greater number of meteoric irons, which exist in the Paris collection, have fallen on the earth at undetermined epochs; all the meteoric stones are of comparatively recent date. Perhaps we are even justified in saying that stones of a new kind are beginning to arrive, for falls of *carbonaceous meteorites* were unknown before the year 1803, and four have been observed since then.

From this assemblage of facts, M. Stanislas Meunier concludes that meteorites are the fragments of one or more heavenly bodies which, at a period relatively recent (for these waifs are never found except in superficial strata), revolved round the earth, or perhaps round the moon. Having, in the course of ages, lost their own proper heat and become penetrated by the cold of space, they have arrived, much sooner than the moon, by reason of their inferior volume, at the last term of the molecular actions which are operating upon our satellite, and which are rendered evident to our eyes by the enormous crevices, the deep fissures with which it is furrowed. Split in all directions, they have fallen to ruin, and their fragments, remaining scattered along the orbit, so as to form a circle more or less complete, have at the same time become arranged, according to their density, in zones concentric with the focus of attraction towards which they are constantly impelled by the resistance of the ethereal medium through which they move. The masses nearest to the centre, and which were principally composed of iron, were the first to fall; afterwards came the stones, in which period we now are. Hereafter, perhaps, will arrive meteorites analogous to our crystallised formations, and perhaps even to our stratified beds.

Thus meteorites, the veritable products of demolition, represent, according to M. Meunier, the last period of the evolution of planetary bodies. The incandescent orb, the sun, figures at the present day in our system as the sole representative of the primitive state through which the earth, and all the other bodies which revolve around it, have passed; the moon representing the future which awaits the terrestrial sphere, now in all the plenitude of life; and, finally, meteorites show us what becomes of the dead stars, how they are decomposed, and how their materials return into the vortex of life.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Dr. Livingstone's Explorations.

It certainly is to be regretted that the information received from Dr. Livingstone should be so imperfect. Still, though insufficient in itself, perhaps, to warrant our arriving at any positive conclusion respecting his claim to have discovered the chief sources of the Nile, the information furnished by him affords material aid towards the solution of that great problem of African geography, and is generally of much greater value, in my estimation, than it would appear to be in that of your learned correspondent "F.R.G.S."

Before adverting to the main subject, I desire to point out, in the first place, that Dr. Livingstone has definitively settled that the Chambeze—the New Zambesi of some of our maps—is not an affluent of the well-known river Zambesi, which flows eastward into the Indian Ocean, but is a distinct stream, of which the course is to the west and north-west. On this point it is due to Mr. Cooley to say, that, although he was mistaken respecting the upper course of the Zambesi itself, he has long contended for the separate existence of the "New Zambesi," or Chambeze.

Secondly, Dr. Livingstone has ascertained that the Chambeze, in its lower course beyond the capital of the Cazembe, is joined by another large river, the Lufira, coming from the south and south-west, which drains the western side of the country south of Tanganyika, as the Chambeze drains the east side. The Lufira was not seen by the traveller; but when he was at some place, not named by him, in 11° S. lat., that river was pointed out to him as being at some distance west of that spot, and was described as being so large there as always to require canoes; for so I read his words:—"I have not seen the Lufira, but, pointed out west of 11° S., it is there asserted always to require canoes;"—which shows that it must come from a considerable distance south of that parallel.

In the next place, Dr. Livingstone informs us that the Chambeze enters Lake Bangweolo, and then changes its name to Luapula; that this river flowing north enters Moero Lake, and "on leaving Moero at its northern end by a rent in the mountains of Rua it takes the name of Lualaba, and passing on N.N.W. forms Ulenge in the country west of Tanganyika." This, it must be remarked, is not native information, but the result of the traveller's own personal observation on the spot. His letters are dated "near Lake Bangweolo;" and in speaking of the Lualaba he says, "I have seen it only where it leaves Moero, and where it comes out of the crack in the mountains of Rua."

To make it more certain that he is speaking of the Lua*laba*, and not of the Lua*pula*, the traveller expresses his intention "to follow down the Lua*laba* and see whether, as the natives assert, it passes Tanganyika to the west, or enters it and finds an exit by the river called Locunda [or Loanda] into Lake Chowambe;" which lake, he says, "I conjecture to be that discovered by Mr. Baker;"—adding, "I shall not follow Lua*laba* by canoes," &c.

Nothing could well be more explicit than this. And yet your correspondent represents Dr. Livingstone as saying that "he saw the Lua*pula* only at this gap in the mountains," and describes the Lua*laba* as being a month's journey further west, and as falling into the Lulua and so joining the Zaire, or great river of Congo, on the west coast of Africa. There must clearly be some mistake here.

I think, too, there must be some misapprehension respecting "the great salt marshes, which chiefly supply the interior of Africa," described by "F.R.G.S." as situated on the banks of the Lualaba, a great running stream of fresh water. Is it not more likely that those salt marshes lie in some extensive depression in the interior of the continent, having no outlet, but in which the rivers that may flow into it are absorbed and lost?

Further, according to Dr. Livingstone, the Lualaba, after leaving Moero beyond the town of the Cazembe to the north, forms Ulenge, either a lake with many islands or a division into several branches, which are taken up by the Lufira. This I understand to mean, that the junction of the Lualaba and the Lufira is in Ulenge, *north* of the Cazembe's residence. "F.R.G.S." says, on the contrary, that the Lufira "flows into the Luapula from the west about 100 miles S.W., or S.S.W., from the Cazembe." How are these two statements to be reconciled?

Then "F.R.G.S." says, "When our author speaks of the Luviri (Lufira) entering Tanganyika at Uvira, he evidently casts the dimly discerned views of the natives into his own preconceived mould, and clothes them in his own language." But Dr. Livingstone could scarcely have had any "preconceived" notions on the subject, unless he took with him Mr. Cooley's map of 1852, in which the Chambeze, under the name of the New Zambesi, is laid down as joining the Luviri and then, under the name of Luapula, falling into the lake of "Zangañika" on its west side in about 8° S. lat. And this opinion Mr. Cooley would seem to regard still as the correct one; for in a letter which appeared in the *Daily Telegraph* of the 27th August last, with his initials "W.D.C.," he expressly states that "the drainage of the Cazembe's country is all into the Nyanza on the east." Though why this name should be applied to the Lake of Tanganyika is not patent. We know the "Victoria Nyanza" of Speke, the "Albert Nyanza" of Baker, the "Lake Tanganyika" of Burton, and the "Lake Nyassa" of Livingstone. We also know that in Mr. Cooley's maps of 1845 and 1852, Tanganyika and the more southerly Lake Nyassa are made to form one continuous body of water under the name of "Nyassa, or the Sea." But the present seems to be the first time that the designation of "Nyanza" has been applied, without any qualification, to the separate Lake Tanganyika. I perceive that "F.R.G.S." associates Captain Burton with this "Nyanza;" but such a name was never given to it by its discoverer, neither is it generally known by any other designation than that of "Lake Tanganyika:" whether or not it should properly be called the "Lake *of* Tanganyika" is of no moment.

I come now to the consideration of Dr. Livingstone's claim to the discovery of the sources of the Nile, which will be best given in his own words: "I think that I may safely assert that the chief sources of the Nile rise between 10° and 12° south latitude, or nearly in the position attributed to them by Ptolemy, whose river Rhaptus is probably the Rovuma." On this "F.R.G.S." acutely remarks: "Here two different problems are attempted to be solved at once—the one touching the sources of the White Nile, and the other those of Ptolemy's Nile;" in which remark he is no doubt substantially correct. Into the question of Ptolemy's sources of the Nile, on which subject "F.R.G.S." and I differ widely, I need not now enter: what I have here to do with, is the question of the chief sources of the Nile. And in order to decide whether Dr. Livingstone has really discovered these sources, it is, in the first instance, requisite to define the limits of the basin of the Nile, so as absolutely to determine where the sources of the river can or can not be situated. As those limits were approximatively determined in a paper "On the Nile and its Tributaries," communicated to the Royal Geographical Society in 1846, and published in the seventeenth volume of the Society's Journal, I cannot do better than reproduce the portion of it relating to this particular subject.

After describing the physical character of the table-land of Eastern Africa, of which Abyssinia forms the northern extremity, and its rivers as far as they were then known,—on which subject I need not dilate, as the substantial correctness of my views is now established,—I proceeded in these terms:—

"All the streams of the plateau or western counter-slope of the Abyssinian chain are affluents of the Nile, and their easternmost branches take their rise at the extreme eastern edge of the table-land, which is the limit of the basin of the Nile, and the watershed between its tributaries and the rivers flowing E. and S.E. towards the Indian Ocean. On the seaward side of this watershed, the declivity being much more abrupt and its extent much more limited, the rivers must necessarily be of secondary importance. Thus, proceeding from the N., we do not meet with a stream deserving of name until we come to the Hawash; and even that river is, near Aussa, lost in Lake Abhebbad before reaching the ocean. The river Haines of Lieutenant Christopher, which is the next in succession, appears, in like manner, not to have sufficient power to reach the sea, at least not at all times of the year. Further to the S. we find the river Gowin (*i.e.* Wabbi-Giweyna) or Jubb, possessing a substantive character as an ocean stream; but this river, during the dry season, has at its mouth a depth of only two feet. At a short distance to the S. of the equator is the Ozay, which river, though said to be of great extent, has very little water at the entrance. Further S. the same law appears to prevail, as is exemplified in the Lufiji or Kwavi (Quavi), the Livuma [Rovuma] and the Kwama (Quama) or Kilimane (Quilimane), which rivers rise on the eastern edge of the elevated plain in which Lake Zambre or N'yassi is situate, and flow into the Indian Ocean. *Here, however, the southern extremity of the basin of the Nile having been passed*, the larger streams of the counter-slope no longer join that river, but take their course westwards into the Atlantic, belonging in fact to a distinct hydrographical basin."

What I thus wrote three-and-twenty years ago requires now but little modification. The erroneous identification of Lake Zambre with N'yassi was simply adopted from Mr. Cooley's learned and valuable paper in the fifteenth volume of the Society's Journal, which was then our only authority on the subject. I also followed him in his alteration of the spelling of the name "Zambre," which in my paper was printed "Zambeze," with the explanatory note, "This name is usually printed Zembere, Zembre, or Zambre. It is the Lake *Maravi* of the maps." Though even this was wrong; for Nyassa is properly Lake Maravi, and Tanganyika is the Great Lake, or Zambre. The blending of the two together by Delille and D'Anville was the primary cause of the long-existing misapprehension of the subject.

In my paper from which the foregoing extract is taken, when speaking of the lakes and swamps of the Upper Nile as then known, I added in a note, "May not Lake Zambre ('Zambeze'), or Nyassi, be the continuation of this series of lakes? In this case it would be simply the upper course of the Nile."

Acting on this suggestion, Professor Berghaus, in 1850, laid down Mr. Cooley's "Nyassi, or the Sea" as the head of the Nile; but, as I pointed out to him, he had under any circumstances carried the river too far south, because the Chevalier Bunsen and I had in the previous year come to the positive conclusion, on the reports of the Church missionaries at Mombas, that Zambre (now Tanganyika) and Nyassa were two separate lakes, a conclusion which every fresh discovery only tended to confirm.

The Cuama and Quilimane mentioned by me were all that we then well knew of the Zambesi, the great western extent of which river only became revealed to us through the former explorations of Livingstone. He thus absolutely closed the basin of the Nile in that direction; though the fact of his having done so was not then demonstrable. When he wrote to Lord Clarendon in February 1867, as he says in his present letter, he "had the impression that he was then on the watershed between the Zambesi and either the Congo or the Nile." His present determination of the want of connection between the Chambeze and the Zambesi, and of the western and north-western course of the former river, has proved the soundness of his impression of February 1867.

The question is therefore now narrowed to this:—Do the united streams of the Chambeze and the Lufira, under the name first of Luapula, and then of Lualaba, flow into the Nile or into the Congo? I am of opinion that they join the former river, and that the explorations of Dr. Livingstone have established the correctness of the views I have long entertained, and especially those enunciated in the *Athenæum*, No. 1,969, of July 22, 1865, on the first announcement by Sir Samuel Baker of his (unconscious) discovery of the main stream of the Nile under the name of "Albert Nyanza," and consequently I believe we are at length enabled to strip the veil from the Nile Mystery.

CHARLES BEKE

Bekesbourne, December 1

Food of Oceanic Animals

UNDER the above head, in a note which appeared in NATURE of the 16th Dec. p. 192, Mr. Gwyn Jeffreys "calls the attention of physiologists to the fact that plant-life appears to be absent in the ocean, with the exception of a comparatively narrow fringe, known as the littoral and laminarian zones, which girds the coasts, and of the 'Sargasso' tract in the Gulf of Mexico." He then proceeds to say that, "during the recent exploration in H.M.S. *Porcupine* of part of the North Atlantic, he could not detect the *slightest trace* of any vegetable organism at a greater depth than fifteen fathoms. Animal organisms of all kinds and sizes, living and dead, were everywhere abundant, from the surface to the bottom . . . some of them being zoöphagons, others sarcophagons, none phytophagons." And, lastly, after asking "whence do oceanic animals get that supply of carbon which terrestrial and littoral or shallow-water animals derive, directly or indirectly, from plants?" and "can any class of marine animals assimilate the carbon contained in the sea, as plants assimilate the carbon contained in the air?" Mr. Jeffreys sums up his conclusions on the subject in the following words:—"At all events, the usual theory, that all animals ultimately depend for their nourishment on vegetable life, seems not to be applicable to the main ocean, and consequently not to one-half (*sic*) of the earth's surface."

As Mr. Jeffreys has been constituted an authority on deep-sea exploration, and now claims the view above cited as original, I must be permitted to point out that he has either forgotten what, at one period, he professed to have read and acquiesced in, in one of my writings; or that, for some unaccountable reason, he now repudiates both my opinions and those which were once his own.

As the entire absence of plant-life, even in its primitive phases, in the deeper abysses of the ocean, and the process whereby the nutrition of the lowest animal forms is secured in the absence of even the rudimentary digestive apparatus which is observable amongst the higher Rhizopods, were fully discussed by me in my "Notes on the Presence of Animal Life at great depths in the Ocean" (p. 27), published in 1860; in my work on "The North Sea-bed" (pp. 131-2), published in 1862; in a note which appeared in the *Annals and Magazine of Natural History* for August 1863 (p. 166); and more recently in two papers contributed by me to the *Monthly Journal of Microscopical*

Science, No. 1, pp. 32-33, and No. 4, pp. 231-2-3, published in the present year,—it will, I think, be admitted that Mr. Jeffreys can hardly claim originality in his statement.

But to prove that Mr. Jeffreys was well acquainted with my previously published observations on the subject, I invite attention to two distinct statements of his which appeared in his Reports on Dredging, and were published in the *Annals and Magazine of Natural History*, on the respective dates given below:—

Annals, Nov. 1866, p. 391.	*Annals*, Oct. 1868, p. 305.
"Dr. G. C. Wallich, in his admirable and philosophic treatise, with which all marine zoologists and geologists are, or ought to be, familiar, believed," &c. &c. "As to the accuracy of his statements, *no reasonable doubt can be entertained.*"	"Coccospheres and Foraminifera cover the bed of the Atlantic at enormous depths. The occurrence, therefore, of such organisms on the floor of the ocean, at great depths, does not prove that they ever lived there. *I should rather be inclined to believe* that they dropped to the bottom when dead, or after having passed through the stomachs of other animals which had fed on them."

It thus becomes manifest that Mr. Jeffreys had studied my writings, but that the opinions entertained by him in 1866 became revoked in 1868; whilst those held by him in 1868 were in turn superseded by views formed and published in 1869! This circumstance is the more significant, inasmuch as Dr. Carpenter, in his "Official Report on Dredging," for 1868 (p. 181), actually singles out the opinion published by Mr. Jeffreys, as above, in the autumn of the same year, as an authoritative illustration of the want of credence which my discoveries had met with!

With regard to Mr. Jeffreys' new division of oceanic animals into *zoophagons* and *sarcophagons*, I have nothing to urge beyond my avowed inability to discern any physiological difference between creatures that are zoophagous and those that are sarcophagous. It only remains for me to express my belief that, up to the present period, I have stood alone in maintaining, against Ehrenberg and others, that plant-life, even of the lowest types, becomes extinct at depths exceeding four or five hundred fathoms; and in endeavouring, by a series of observed facts, to prove that the nutrition of the Foraminifera and certain other oceanic Rhizopods is effected by a special vital process, which enables them to eliminate and apply to the formation and sustenance of their body and shell-substance, through their surfaces only, the materials which exist in the medium in which they reside.

Kensington, Dec. 21 G. C. WALLICH

Colouring of the Cuckow's Egg

As I see Professor Newton has, in his very interesting paper on Dr. Baldamus' theory of the colour of Cuckoo's eggs, noticed my "stigmatising" the Doctor's theory as "wild," in my "Birds of Somerset," will you be kind enough to allow me space for a few lines on the subject? Although it is with great diffidence that I venture to differ from Professor Newton, I still cannot help considering Dr. Baldamus' theory as "wild," not perhaps as it appears under the manipulation of Professor Newton, for he seems to me to have pruned and pared it down so nicely that there is but little of the original left; and I think he would not much differ from me in my opinion as to the wildness of the theory, if he had to accept all the allegations in Dr. Baldamus' paper published in *Naumannia*:* For instance, compare the following passage in Professor Newton's paper in No. III. of NATURE with some passages from Dr. Baldamus' paper:—"Having said thus much, and believing as I do the Doctor to be partly justified in the carefully-worded enunciation of what he calls 'a law of nature,' I must now declare that it is only 'approximately,' and by no means universally true, that the Cuckow's egg is coloured like those of the victims of her imposition. Increase as we may by renewed observations the number of cases which bear in favour of his theory, yet, as almost every bird's-nesting boy knows, the instances in which we cannot, even by dint of straining our fancy, see resemblances where none exist, are still so numerous as to preclude me from believing in the generality of the practice imputed to the Cuckow. In proof of this I have only to mention the many eggs of that bird which are yearly found in nests of the *Hedge-Sparrow* in this country, *without ever bearing the faintest similarity to its well-known green-blue eggs.* One may grant that an ordinary English Cuckow's egg will pass well enough, in the eyes of the dupe, for that of a Titlark, a Pied Wagtail, or a Reed Wren, which according to my experience are the most common foster-parents of the Cuckow in this country; and indeed one may say, perhaps, that such an egg is a compromise between the three, or a resultant, perhaps, of the three opposing forces; *but any likeness between the Hedge-Sparrow's egg and the Cuckow's so often found alongside of it, or in its place, is not to be traced by the most fertile imagination.* We must keep, therefore, strictly to the letter of the law laid down by Dr. Baldamus, and the practice imputed to the Cuckow is not universally, but only approximately true." This certainly is very different from Dr. Baldamus' own statement:—"If Mr. Braune, the forester of Griezland, had not cut this large Willow Wren's (*Shippolais*) egg (as it seems) out of the ovary of the Cuckoo, which was killed as she was flying out of the Willow Wren's nest; if Count Rödern, of Breslau, was not a reliable authority that this apparent Redstart's egg was taken out of the nest of the Redstart (*Ruticilla phœnicurus*); if M. Halricht had not taken this large Tree Pipit's egg out of the nest of a Tree Pipit (*Anthus arboreus*); if I myself had not taken out of the nests of the Red-backed Shrike (*Lanius collurio*) this reddish and this green-greyish peculiarly marked Cuckoo's egg, one might indeed entertain doubts whether this variously-coloured collection—these *green eggs, with and without markings;* these on white, grey, green, greenish, brownish, yellowish, reddish, and brown-reddish ground; these grey, green, olive green, ash grey, yellow brown, yellow red, wine red, brown red, dark brown and black; these spotted, streaked, speckled, grained and marbled eggs could one and all be the eggs of our Cuckoo! And yet this is indeed the fact!" How different this from the much more cautious and limited statement of Professor Newton, first quoted, which would entirely sweep away some of these varieties, especially those resembling the eggs of the Redstart or the Hedge-Sparrow, for the eggs of these two species do not differ much from each other, and what might be said of the eggs of the one would apply equally to those of the other; yet these are two of Dr. Baldamus' selected species, for, a little further on, he gives a list of the various species from the nests of which Cuckoo's eggs have been taken resembling those of the foster-parent. Of the eggs of the Redstart he says:—"These four specimens, which were found in the nests of *Ruticilla phœnicurus*, are all of a light-green ground colour; two of them have the larger and more or less brownish spots, which on one of them form a zone; the third has similar markings, but only sparingly scattered over the whole surface, whilst the fourth is without any marking at all—herein it is identical with one in the possession of Dr. Dehne, which is *uniformly light-greenish blue, without any markings whatsoever.*"

Of the single specimen of the egg resembling that of the Hedge-Sparrow, No. 15 in his list, he says:—"One of the most interesting of the Cuckoo's eggs is a beautiful blue-green one, which was taken out of the nest of *Accentor modularis, without any markings*, and which even to the shell, the grain, and the size (bis auf Shale, Korn, und Grösse) is like a very dark egg of the Hedge-Sparrow." On reading this quotation from the statement of the facts on which his theory is founded by Dr. Baldamus in the paper in *Naumannia*, and comparing it with Professor Newton's paper above quoted, we cannot help seeing that there is a decided issue of fact between them, especially as to the eggs of *Accentor modularis*.

The conclusion which Dr. Baldamus draws from the facts stated by him is that Nature, by means of such arrangements, has ensured and facilitated the preservation of a species otherwise much exposed to danger, and that she has attained this object by investing every hen Cuckoo with the faculty of laying eggs coloured exactly like the eggs of the bird of whose nest she prefers to make use, according to the locality. Now if this were really the case, and it were really true that this colouring of the eggs were essential for the preservation of the species, would it not be just one of those laws of Nature which we should expect to find universal, or so nearly so that there would be but very few exceptions? But according to Dr. Baldamus himself the exceptions are numerous, and Professor Newton would make them still more numerous, and would no doubt be quite right in doing so. How, then, do the eggs in the exceptional cases prosper? Does the Hedge-Sparrow or the Redstart throw the egg of the Cuckoo out of its nest because it does not resemble its own? or do the birds to whose tender mercies the Cuckoo, according to Dr. Baldamus himself, is occasionally obliged to entrust its eggs when it cannot find a fitting nest in which to place them, do so? This does not appear to be at all

* Where I have quoted from this paper, I have quoted from the translation by the Rev. A. C. Smith, published in the *Zoologist* for 1868, which professes to be an accurate translation, and there seems to be no possible reason to doubt its being so.

the case, but the eggs remain in the nest in which they were originally placed by the parent Cuckoo, and are duly hatched by the foster-parent. That being so, the necessity for the law of nature which the Doctor wishes to establish falls to the ground. I do not like to put forward my own opinion against such great authorities as Dr. Baldamus and Professor Newton, but I think the inquiry now set on foot in this country by the publication in English of Dr. Baldamus' paper in *Naumannia* will be to show that Cuckoo's eggs do not in fact vary from each other more than those of many others, and that the resemblances to the eggs of many other species are not greater than sometimes arises in many ordinary cases.

CECIL SMITH

The Cloaca Maxima

YOUR correspondent "Ignoramus" will find some account of the drainage of Rome in Pliny ("Hist. Nat." xxxvi. 15, s. 24). He will also find further particulars in Livy (i. 38), and in Ulpian ("Dig." 43, tit. 23, s. 1).

History repeats itself. Just as the London sewers were originally natural brooks or artificial ditches by which the rainfall of the district was carried off, and into which it was penal, down to the year 1815, to turn any "sewage" proper; so the Cloaca Maxima was built originally, in very early times (by Tarquinius Priscus, according to Livy), to carry off the rain-water from the Forum. Afterwards, however, all kinds of liquid refuse were allowed to find their way into it; and this seemed such a convenient way of getting rid of troublesome matter, that the whole city was eventually undermined by a network of sewers, including small pipes of wood and earthenware connecting the houses with the main sewers. Whether "traps" were also used I am unable to say, but I think it very probable that some simple combination of trap and cess-pit, in masonry, was used to prevent an up-blast of foul gas into the *atrium*.

What became of the solid refuse I do not know, but from all that I can gather I imagine it must have been carted away periodically. I trust some of your readers may have compassion for our ignorance, and, by enlightening us on this point, completely restore to "Ignoramus" that peace of mind which he lost in early childhood.

I trust also that the days of river cloacal pollution, in this country at least, are numbered, and that the advances which other sciences have made in the last 2,000 years will at last make our engineers ashamed of their ignorant violation of what I hope I may be allowed to call one of the laws of Nature.

W. HOPE

Hydro-carbon Colours

CAN your readers inform me of any book in which I can get to know all that is known on the "Hydro-carbon colours, and their application to Art industry," or direct me to any sources where the information can be obtained?

Plymouth, December 18 T. W. FRECKELTON

NOTES

THE *Journal of Botany* will pass into new management with the commencement of the year. The leading English botanists have promised their co-operation towards making it a complete record of the progress of botany at home and abroad during the month. It will in future be edited by Mr. W. H. Trimen, M.B., of the British Museum, author of "A Flora of Middlesex."

THE persistent decrease in the yield of our sea-fisheries has assumed a serious aspect, and urgently calls for systematic investigation at the hands of the Government. The usual machinery for such investigations, namely, a Royal Commission, could, however, hardly obtain the exact kind of information necessary for a determination of the probable cause of the mischief. Nothing short of the appointment of Inspectors of Sea Fisheries, with analogous functions to those discharged (with such beneficial results) by the Inspectors of Salmon Fisheries, can afford the opportunity for a thorough examination of the subject, and prepare the way for useful legislation. This course is ably advocated in the last number of *Land and Water*, and we feel it incumbent upon us strongly to second the recommendations of our contemporary on this point.

THE Ethnographical Section of the Geographical Society of Berlin, which has existed in a more or less definite form for about three years, has just separated itself from the parent organism, and entered upon an independent career as the Society for Anthropology and Ethnology. The first ordinary meeting of the new society took place on the 10th instant, when a paper was read by Professor Virchow on the North-German Pile-works. As compared with the great majority of such remains in Switzerland and South Germany, the pile-works of the North are not of very high antiquity. There is only one colony, that of Wismar, which belongs to the Stone period; even the older forms of bronze are rarely met with. The mode of construction of the pile-works likewise indicates an advance on that employed in Switzerland. Professor Virchow is of opinion that some, at least, of the earthworks found in certain districts are contemporary with the lake habitations: evidence on this interesting point is promised at some future time. That the pile-works, although of comparatively recent date, are really pre-historic, is indicated by the discovery of the remains of beaver and elk. The latter animal is not mentioned by the old chroniclers of Brandenburg and Pomerania; neither do we find mention of any lake-dwelling people in the ancient Scandinavian or Polish historians.

WE understand that steps are being taken to found an anthropological society in Hamburg, but no particulars have as yet reached us.

WE extract the following from the last Weekly Bulletin (26th inst.) of the Scientific Association of France:—"The vine occupies in France almost 2,500,000 hectares (6,175,000 acres). This constitutes the one-and-twentieth part of the French territory, and the sixteenth part of its soil capable of cultivation. The gross produce amounts to more than 1,500,000,000 francs. This industry occupies six million men, women, and children, and nearly two million merchants, agents, traders, &c. Sixty-nine departments cultivate the vine, from the Gironde, which reckons more than 150,000 hectares (370,500 acres), to the department of Ille-et-Vilaine, which only possesses 104 hectares (256 acres)."

THE commission appointed by the Imperial Academy of Medicine in Paris to investigate the subject of vaccination has just concluded its labours by the presentation of its Report, which has been adopted.

MR. J. MIERS, so well known for his researches in the Botany of South America, is about to publish the second and third volumes of his "Contributions to Botany," which will include a complete monograph of the *Menispermaceæ*, and of the South American species of *Ephedra*, showing that this genus does not belong to the Gymnosperms or naked-seeded plants, as generally believed.

IN a letter of the 17th ultimo, addressed to the *Astronomische Nachrichten*, Dr. Oppolzer discusses the observations of a faint comet discovered by Pons in February 1808, and arrives at the conclusion that it is exceedingly probable that the comet referred to is identical with that named after Winnecke. Dr. Oppolzer is at present engaged in working out the observations of the latter comet, more especially in reference to its supposed identity with Comet II. of 1766.

WE regret to learn from the recent report of the Miners' Association for Cornwall and Devonshire, that that useful body is in danger of being dissolved in consequence of the inadequate support it receives from the mining interest. The importance of combining scientific knowledge with practical experience, if we intend to maintain our present position in mining and metallurgy as against the highly-trained miners of other countries, is acknowledged by every competent person. Surely, then, when owners of mines and shareholders in mining companies learn that the Miners' Association not only discusses and publishes important scientific papers of a practical character, but is at the present moment educating in its classes more than a hundred young men in chemistry, mineralogy, geology, and mining, they will not suffer so important an institution to die out or languish for want of funds. Mr. Robert Hunt, F.R.S., keeper of the Mining Records, is the hon. general secretary of the association. The Report for 1869 is published at Truro (Heard and Sons), and is to be had for a shilling.

BENZOL has been applied to a somewhat novel purpose. If poured on a piece of ordinary paper, immediate transparency is produced, to such an extent as to enable one to dispense entirely with tracing-paper. On exposure to air, or, better, a gentle heat, the liquid is entirely dissipated, the paper recovers its opacity, and the original design is found to be quite uninjured.

WE are glad to learn that the acceptance, by Dr. Czermak, of an honorary professorship in the University of Leipzig is likely to lead to a departure from the rule hitherto observed in the German universities, of treating physiology as an integral part of the medical course. No doubt lectures on general physiology, with a more particular view to the special requirements of the medical student, will always be necessary; but the claims of the general student to a sound knowledge of the principles and methods of this science can no longer be ignored. Independently of the fact that physiology deals with subjects of the highest possible general interest, it must not be forgotten that in its present stage of development it can hardly be looked upon otherwise than as an extension of the physical and chemical sciences. The lectures which Prof. Czermak contemplates giving for the general benefit of the University of Leipzig are not intended to be of a so-called popular nature. They will be of the same general character as the ordinary lectures on physics, logic, or general history. The Professor insists very strongly upon the absolute necessity of direct observation for a thorough understanding of the subject; and it is solely the want of a suitable theatre and apparatus for enabling large audiences to view physiological experiments, that prevents his entering upon the promised course of lectures this winter. Dr. Czermak spoke so eloquently and so thoroughly in earnest on this subject on the occasion of his recent installation as Honorary Professor, that we make no doubt he will be able to carry out his plans successfully during the ensuing summer term.

WE have a fresh illustration of the intimate alliance between science and commerce. Mr. Winwoode Reade recently set out from Sierra Leone to explore the interior, the funds of the expedition being defrayed by the munificence of Mr. Andrew Swanzy, a London merchant. Communications have been recently received stating that Mr. Reade, travelling on a line to the south-east of the routes of Park and Caillie, has reached a point farther south than any of his predecessors. The solitary traveller, after surmounting many difficulties, was rewarded by reaching a hitherto unknown town named Farabana, situate about 10° N. lat. and 10° W. long. He had crossed several rivers, flowing we presume from the watershed of Mount Loma, and was among the head-waters of the River Niger. The town, Farabana, contains about 10,000 inhabitants, well-disposed, and eager for trade. Mr. Reade mentions his having experienced protection and help from the Sultan of Bornir; we suppose, by orders issued to his subordinate chiefs and headmen, in this outlying district of his kingdom. We may hope that Mr. Reade's discoveries will enrich our maps with accurate geography of the country to the north of the Cong Mountains, as marked on the maps, and of the Niger from its source to the point where previous travellers have struck its stream.

THE theory of the derivation of the primitive population of Western Europe from an African source is likely to receive some confirmation from recent researches in Algeria. A Mr. Faidherbe, who has examined a necropolis of 3,000 Megalithic graves at Roknia, in the province of Constantine, reports that the skulls obtained have led him to the conclusion that the Berbers were the original people of the Atlas; and that they do not resemble any African or Semitic race, but rather the earliest inhabitants of Western Europe.

THE "Transactions of the Swedish Academy of Sciences for 1868" contain a paper proposing the use of the reindeer moss and various other species of lichen as a material for the manufacture of sugar and alcohol. By means of dilute sulphuric or muriatic acid, the cellulose of the plant is turned first into dextrine, and then into grape-sugar. No experiments on a large scale have as yet been made, but the author of the paper is sanguine as to the economic success of such an undertaking. Of the other papers printed in this volume of "Transactions," we may mention the following:—"On a remarkable species of sponge living in the North Sea," by Professor Sven Lovén, and "Swedish and Norwegian Diatoms," by P. T. Cleve. These communications are illustrated by drawings. The other papers, with the exception of three by Edlund, detailing researches in reference to the electric spark, relate chiefly to the fauna and geology of various parts of the Swedish kingdom. The Memoirs of this Academy for the year 1868, containing the more important papers presented, have not yet reached us.

THE Native Guano Company, now successfully treating the sewage of the town of Leamington by the A.B.C. process, have applied to the Metropolitan Board of Works to enter into a treaty with them for the concession of the sewage on the south side of the Thames. The question has been referred to the Works Committee. Should the concession be granted, the movements of the company will be watched with great interest, as their success or failure will tend greatly to settle the question of the possibility of making the purification of the sewage of *great towns* a commercial success.

HERR KARL BRUHNS, director of the Berlin Observatory, is preparing for publication a scientific life of Humboldt, to which several illustrious German scientific men have promised to contribute. The first portion, from the pen of Dr. Ave Lallemand, will contain the life, properly so called, of Humboldt. The second part will be devoted to an account of his researches and discoveries. This latter part will occupy eight chapters, and will be confided to writers possessing special qualifications for the task. Persons having in their possession unpublished materials relative to the life or labours of Humboldt are requested to transmit them to Herr Bruhns.

OYSTERS are now so dear in London that we may reap some contentment by learning that they are sold wholesale in San Francisco, at the rate of six shillings a dozen. These oysters are said very much to resemble our "natives;" being round, fat, full-flavoured, and very good; but they do not suit the taste of those who have long enjoyed the luxury of the large, delicate molluscs of the Atlantic seaboard. There are fine beds of the long-shelled oyster in the Gulf of California, and as they will not grow in the Pacific, they are transported 1,700 miles by steamer to "Frisco;" about half the cargo dying on the passage. Notwithstanding all the oyster controversy and oyster literature of recent years, it is still very hard to understand why they should be so dear in London. At Van Laar's shop, in the Kalverstraat, at Amsterdam, the very finest oysters, thought by many to be much superior to the "natives," may be eaten at the rate of 50 cents (10*d.*) the dozen.

THE first part of a Hand-List of Genera and Species of Birds, by Mr. G. R. Gray, has just been issued from the British Museum. It includes the *Accipitres*, *Tenuirostres*, and *Dentirostres*, and forms an octavo volume of 400 pages. All the recognised genera, sub-genera, and species are enumerated, and not merely the species represented in the national collection. The latter are, however, specially indicated. Some notion of the marvellous variety of bird-form may be gathered from the fact that this volume gives the name and habitat of no less than 6,057 species. The second and concluding volume is stated to be far advanced towards completion. We have also to chronicle, for the benefit of our entomological readers, the appearance of Part II. of the Catalogue of Specimens of *Dermoptera Saltatoria* in the British Museum, by Mr. Francis Walker.

A LARGE depôt of petroleum has just been discovered in the Caucasus. It is situated on the east of the Caspian, where there are large numbers of these springs, many of them occurring in close proximity. This new spring is said to be capable of producing 40,000 livres daily. The American method has recently been adopted with the greatest success.

DR. ROBINET, formerly president of the Paris Academy of Medicine, member of the Municipal Council, and at one time president of the Hygienic and Sanitary Commission of the City of Paris, has just died. His decease was due to an affection of the chest, contracted whilst on a scientific expedition in Germany. Dr. Robinet had completed his 72nd year.

IT appears that the surface glass which contains soda undergoes considerable change after a lengthy exposure to the air. Bluish glass undergoes no such alteration, but that which has originally a greenish tinge becomes brown after a time, whilst very pure white deteriorates rapidly, showing first a yellow, then a brown, and finally a violet film. At this season of the year we do not require this additional colouring to the appearance of our already discoloured atmosphere. It has been noticed that some modern stained glass on a foggy day has almost the richness of the ancient. We need not go far for a solution of this. The old glass has acquired in the course of ages a film which takes the place of a permanent fog, especially on those colours which, like the ruby, are formed by a thin coating of the coloured glass on a thicker plate of transparent metal.

THE Agricultural Society of France has recently addressed the following questions to each of its members, and to the presidents of all the French Agricultural Associations:—"1. Can the depreciation in the price of wool be remedied; and, if so, by what means? Does the rise in the price of meat afford a sufficient compensation to the producers of wool? 2. Do the production and sale of cereals meet with any obstacle demanding the attention of the legislator? 3. Is there any defect in the facilities for increasing the domestic consumption or the exportation of wine? 4. Have the agricultural industries, especially those which produce alcohol and sugar, any need o modification as regards the economic regulations to which they are subject? 5. Are there in your district any other branches of agricultural produce suffering from a crisis to which it would be necessary to call public and legislative attention?"

WE have been requested to state that the cable laid between Salcombe and Finisterre (Dec. 2nd) was manufactured at W. T. Henley's Telegraph Works, North Woolwich.

SCIENTIFIC SERIALS

IN the *Annales des Sciences Naturelles* (Zoologie, Tome xii. Nos. 3 and 4), M. Marcy continues his elaborate paper on the flight of Insects and Birds. Prof. E. Lartet describes and figures *Trechomys Boudnellii* and two other fossil rodents of the Eocene of Paris. New observations on the Zoological Characters and Natural Affinities of the Æpyornis of Madagascar are given by MM. Alphonse Milne-Edwards and Alf. Grandidier. Their paper is illustrated by a fine series of figures of the bones of these gigantic fossil birds: even the enormous bones of the lower limb are drawn the size of nature. The present double number of the *Annales* is concluded by a communication from M. Edward Perrier, entitled "Researches on the *pedicellaria* and *ambulacra* of star-fishes and sea-urchins."

THE November number of the *Annales de Chimie et de Physique* contains the termination of a long memoir by Lecoq de Boisbaudran, on Supersaturation; a memoir by Des Cloiseaux, on Gadolinite, a mineral whose anomalies are very lucidly connected and explained; a very interesting paper by Boussingault, on the Function of Leaves, in which the influence of light is studied as affecting the decomposition of carbonic acid; Observations on a Note of M. Velter as to the agricultural utility of salt, by Peligot; a Chemical Study of Egyptian wheat, by Aug. Houzeau; the Polarisation of the Blue Light of Water, by J. L. Soret (taken from the Geneva *Archives*); and an account of Roberts's elegant experiment, showing the increase of volume undergone by palladium in combining with hydrogen.

THE November number of Reichert and Du Bois Reymond's *Archiv fur Anatomie* contains the following papers:—"The Influence of Artificial Respiration on Reflex," by Dr. P. Urspensky, of St. Petersburg; "Musculi subcrurales et Subanconaci," by Dr. M. Kulaewsky; "The 'Ramus collateralis ulnaris nervi radialis again," by Professor W. Krause, of Göttingen; "The Inter-arytænoid Cartilage of the Human Vocal Organs," by Professor H. von Luschka, of Tübingen (plate); "On the Influence of the Curara Poison on the Electromotor Power of Muscles and Nerves," by Hermann Rocher; "The Nervi Splanchnici and the Ganglion Cœliacum," by F. Bidder, of Dorpat; "On the Musculus Broncho-œsophagus Dexter," a communication by Dr. Wenzel Gruber, Professor of Anatomy at St. Petersburg.

POGGENDORFF's *Annalen der Physik und Chemie*, 1869. (No. 11. Vol. cxxxviii. Part 3). The physical papers in this number (the last published) are:—

(1.) "On the applicability of Ohm's Law to Electrolytes, with a numerical determination of the Electrical Resistance of dilute sulphuric acid by means of alternating currents," by F. Kohlrausch and W. A. Nippoldt (pp. 370 to 390). This paper forms the continuation and conclusion of one begun in the previous number of the "Annalen." After discussing the special difficulties that lie in the way of accurate determinations of the galvanometric properties of electrolytes, the authors show how the most important of them, the polarisation of the electrodes, may be overcome by substituting for a continuous current in one direction a rapid succession of currents of short duration in opposite directions. Such currents were obtained by the rotation of a steel magnet inside a coil of wire; and the employment of them necessitated the use of a Weber's bifilar dynamometer, instead of an ordinary galvanometer. There is a full discussion of the action of the rotating magnet, showing the mean electromotive force due to a given velocity of revolution, and the action of the resulting current on the dynamometer. In the part of the paper now published, the strength of the current traversing a column of dilute sulphuric acid is proved to be proportional to the electromotive force even when the latter does not exceed $\frac{1}{74}$ part of that of a Grove's cell. By using thermoelectric currents, the proportionality between electromotive force and strength of current, in the case of solution of sulphate of zinc between amalgamated zinc electrodes, is shown to hold good even when the electromotive force is only $\frac{1}{429000}$ of that of a Grove's cell. The paper concludes with a series of numerical determinations of the specific resistance of dilute sulphuric acid of various degrees of concentration, from which we quote the following:—At 22° C. the maximum conducting power is possessed by sulphuric acid of specific gravity 1·233 (containing 31·5 per cent. hydric sulphate); taking the conducting power of mercury at 0° as unity, the conducting power of such acid is 0·000077274.

(2.) "On a Comparable Scale for Spectroscopic Observations," by A. Weinhold (pp. 417 to 439). In order to compare the indications of various spectroscopes, the author proposes to denote the various parts of the spectrum by reference to the interference-bands seen in the spectrum of light reflected from a thin plate of biaxial mica; and to reduce the results obtained by the use of plates of various degrees of thickness to a common denomination, by taking two definite parts of the spectrum, *e.g.*, Fraunhofer's lines D and F, as fixed points, and dividing the interval between them into 100 parts. The bands of the interference-spectrum then become comparable with the divisions on an arbitrarily graduated thermometer, the value of which is determined by observing two fixed temperatures. The paper contains a full and careful description of the way of carrying out the proposed method in practice.

(3.) "Experiments on Retarded Ebullition" (third part), by

G. Krebs (pp. 439 to 448). The author describes experiments, with tiresome fulness of detail, in proof of the fact that the pressure upon water which has been long boiled may be reduced considerably below the maximum tension of aqueous vapour at the temperature of the water, without ebullition taking place; but if, under these circumstances, a further sudden diminution of pressure takes place, or if the water is heated, very rapid or even explosive ebullition is liable to occur.

(4). "Lightning without Thunder," by Prof. Th. Hoh (p. 496). In the night between the 25th and 26th July, the author observed *forked* lightning unaccompanied by thunder.

The other papers in this number are: "Investigation of Mica and allied minerals," by M. Bauer (pp. 337 to 370); "Studies of the oxygen-compounds of the Halogens," by Hermann Kämmerer (pp. 390 to 417); "Mineralogical Communications" (eighth part), by G. von Rath (pp. 449 to 496).

BOTANY

The Diffusion of Plants

PROF. DELPINO, of Florence, has published some interesting researches on the relation between the diffusion of plants and animals. The life of every plant has three principal objects: its nourishment, its reproduction, and the distribution of its seeds; for each of these three objects special bio logical conditions being requisite. The fertilisation of many plants can be effected only by some particular animal; as *Arum italicum*, *Aristolochia*, and *Asarum*, by gnats; the fig tribe by different species of *Cynips* (or gall-fly); *Arum dracunculus*, *Stapelia*, and *Rafflesia*, by blue-bottle flies; many others by different kinds of flies or bee-like insects (*Hymenoptera*), and some even by small birds belonging to the family of *Trochilidæ*, or humming-birds; *Rosa*, *Pæonia*, and *Magnolia grandiflora*, by beetles of the chafer tribe; others again by small slugs. If in any particular locality the animal necessary for the fertilisation of a particular plant is absent, it is certain that the plant cannot spread; and thus the conditions for the diffusion of plants are dependent on the geographical distribution of animals. A remarkable illustration is furnished by two plants belonging to the same genus, grown in the botanic gardens in Italy, *Lobelia syphilitica* and *L. fulgens*; the flowers of the former are abundantly visited by *Bombris terrestris* and *italicus*, and freely produce seeds; the latter, notwithstanding its beauty and its great store of honey, is never visited by insects in the neighbourhood of Florence, and never bears seeds spontaneously, but can be readily fertilised by artificial impregnation. Prof. Delpino conjectures that it is naturally fertilised by humming-birds. He believes that the scarlet colour of the corolla, so common in the tropics, but comparatively rare with us, is especially attractive to small birds, but offensive rather than otherwise to *Hymenoptera*. As a rule, scarlet flowers are large, bag-like in form, horizontal in position, and with the nectar completely separated, which would of itself perfectly prevent their fertilisation by insects. The largest European flowers, such as the pæony and large bird-weed (*Convolvulus sepium*) are fertilised by sphinxes and rose-chafers. [Botanische Zeitung.]

The Victoria Regia

THIS magnificent plant has thriven to an unprecedented degree during the past summer in the Botanic Garden at Ghent. Several leaves have attained a diameter of nine feet, and have supported a weight of 250 lbs., and one even the enormous weight of 500 lbs. Seven of the gigantic leaves completely covered the basin of 164 feet square, and they were obliged to be removed to make room for the young leaves which continued to develop in the centre. Every four or five days a fresh flower appeared, which lasted only two days, or rather two nights, opening in the morning of a perfectly white colour, diffusing about five or six P.M. a very powerful odour of vanilla, closing the next morning at 8 or 9 A.M., opening the same day towards evening, this time of a beautiful carmine, and finally closing the next morning. The magnificent leaves last through the summer; the plant begins to dwindle in October, and dies towards December. About this time the seeds, which have been obtained by artificial fecundation, arrive at maturity. They are sown in January, and appear above the ground in about six weeks. Their infancy is very critical; but once past this period, the young plants grow with astonishing rapidity; the plant in the Ghent Botanic Gardens, unquestionably the finest that has ever been cultivated, arrived at its full development in five months.

CHEMISTRY

Lenz on Electrolytic Iron

THE remarkable results of Graham's experiments on the occlusion of gases have induced Lenz to examine the relation of galvanically-deposited iron to this important function. With the aid of a Sprengel pump and apparatus differing but little from that employed by Graham, he has arrived at the following conclusions. Iron and copper, prepared by the reducing action of a galvanic current, contain gases, hydrogen more especially. The volume of the gas absorbed by iron varies within very wide limits, but may amount to 185 times the bulk of the iron, to the surface of which its presence is principally confined. The gas extricated from such iron, at temperatures under 100°, consists almost solely of hydrogen.

MINERALOGY

Des Cloiseaux on Gadolinite

THIS rare mineral has been studied by different crystallographers with apparently contradictory results. Haüy, Phillips, Lévy, Scheerer, and Waage have included it in the clino-rhombic system; Miller, Nordenskiöld, and Von Lang regard it as orthorhombic. The question could not be definitively settled by angular measurements, inasmuch as the primitive prism is a limiting form, bearing upon the corresponding elements of its anterior and posterior portions modifications whose incidences only differ by a few minutes. The author showed in 1860 that some species of gadolinite are mono-refractive, some bi-refractive, and some are mixtures of those two kinds; but it was not until the summer of last year that he was able to accumulate sufficient material for an exhaustive investigation. It now appears (1) that the Hitteröe crystals measured by Waage and the author, and analysed by Scheerer, have an energetic bi-axial refraction on two optic axes; the orientation of these axes, that of their bisectrix and their *inclined* dispersion, prove that the primitive form is an oblique rhomboidal prism, whose plane of symmetry is the same as that of the axes: this variety contains 10 to 12 per cent. of glucina. (2) The most homogeneous of the Ytterly crystals, measured by Von Lang and analysed by Berlin, are mono-refractive; they exhibit a certain number of peculiar modifications, in addition to those shown in the Hitteröe crystals, of which they are the pseudomorphs; and they do *not* contain glucina. (3) The heterogeneous specimens are forms in transition from the first to the second variety; they contain from 2 to 6 per cent. of glucina. These three kinds of gadolinite differ entirely in their symbolic chemical relations. The bi-refractive kind has the formula $\dot{R}_3\ddot{Si}$; the mono-refractive is a sort of peridote, $\dot{R}_2\ddot{Si}$; and the transition forms give an undecided result, the ratio between the oxygen of the silica and that of the bases varying from 3 : 4 to 4 : 5. These differences of constitution probably originate in local circumstances. The Hitteröe mineral seems associated with malacon and polycrase, in a granitic vein composed of quartz, orthose, and oligoclase (with a little mica), and crossing the "gabbro" of which the greater part of the island of Hitteröe is formed: but that of Ytterby is chiefly accompanied by yttrotantalite and fergusonite, and imbedded in a red lamellar orthose, divided by large plates of black mica. [Ann. Ch. et Phys. (4) xviii. 305.]

ZOOLOGY

Development of Sacculina

IN a note, published last February, on the development of the egg in those curious crustacean parasites, the *Sacculinæ*, M. Gerbe stated that the ovules of these animals are formed at first of two transparent vesicles or cells, each furnished with a nucleus and a common membrane; that one of these cells enlarges considerably, and that at the maturity of the ovum, the large cell in which the elements of the vitellus have been developed predominates to such an extent that the smaller one forms only a minute prominence at one pole of the ovum. M. Gerbe compared the large cell to the yolk in the eggs of birds, and regarded the small one as representing the germ or cicatricula. This homology was also applied by him to the ova of the *Arachnida* and *Myriopoda*.

M. E. van Beneden finds that the ovules are not at first composed of two closely applied cells, but that they form a single cell, formed of a transparent protoplasm, containing a few strongly refractive globules, and of a vesicular nucleus with a nucleolus. With these are observed others of an elongated form, and possessing two nuclei, but showing no signs of division, and others, again, which present at one end a small bud, the size of which increases until it equals that of the mother-cell, when one of the nuclei passes into the daughter-cell, and as the division between the two cells becomes more distinct, the appearance described by M. Gerbe is produced. M. van Beneden could could not, however, detect any cell-membrane.

The development of the ovule then goes on much as described by M. Gerbe, one of the daughter-cells being enlarged much more rapidly than the other, and acquiring a vitelline character. When it has attained a diameter of 0·015—0·018 millimetre, a cell-membrane (vitelline membrane) may be detected, which, however, only covers the larger cell. With these ova others are found in which the smaller or polar cell is no longer to be distinguished, but which present at one point a depression representing the surface to which it was attached: the ova when deposited never present the least trace of the polar-cell; but after oviposition the ovaries contain numerous cells, resembling the original mother-cells, which are really the polar-cells thrown off from the mature ova. These, M. van Beneden believes, *become the mother-cells of a new set of ovules.* He supports this opinion by several instances derived from crustacea of other groups, such as *Caligus*, *Calvella*, *Lernanthropus*, *Congericola*, *Anchorella*, *Lernæopoda*, &c., in which analogous phenomena occur.

M. van Beneden remarks, that in the ova of *Sacculina* segmentation of the whole contents of the ovum takes place, and he describes the process. This, as he says, excludes the idea of a cicatricula, which occurs only where a great part of the nutritive material exists outside the protoplasm of the ovicell, as in birds. Hence there can be no comparison between the egg of the *Sacculinæ* and that of birds, nor has it any special analogy to that of the *Arachnida* and *Myriopoda*.

SOCIETIES AND ACADEMIES

London

Ethnological Society, December 21.—Prof. Huxley, LL.D., F.R.S., president, in the chair. An ancient calvaria, which has been assigned to Confucius, was exhibited and described by Prof. Busk, F.R.S. This calvaria was formerly set in gold, richly ornamented, and mounted on a tripod, probably for use as a drinking vessel. It was taken from the Emperor of China's Summer Palace at Peking. The author has discovered four figures upon the skull in faint relief; that upon the frontal portion being the letter A in a Tibetan form of Sanskrit, referable to about the seventh or eighth century of our era. The skull was evidently that of a male advanced in age, but all the evidence tended to show that it ought not to be attributed to Confucius. The President suggested that those portions of the skull which now appear sculptured in relief might have been originally covered with some solid material which would have served as a protection, while the surrounding surface was worn down by constant handling. The Australians still use calvariæ, ornamented in a like manner. Mr. Fergusson alluded to the character of the workmanship displayed by the ornamentation, which had been barbarously removed. He regarded the skull as that of a distinguished personage—either a friend or a foe of some Chinese emperor; and thought that its use as a drinking-cup was supported by a passage in "Herodotus." Mr. Mummery, the present owner of the calvaria, explained the curious manner in which it came into his possession. Dr. Campbell referred to the Buddhist practice of using human thigh-bones as trumpets for calling to prayers. Mr. Donovan regarded the skull, from its small size, as belonging to an uneducated female.—At the same meeting Major Millingen, F.R.G.S., read a long paper on the "Koords and Armenians," in which he gave his reasons for identifying the modern Koords with the ancient Karduks mentioned by Xenophon. The language spoken in Koordistan is entirely different from either Persian or Turkish, and is said to be divided into several dialects. The Koords were described as a rapacious and faithless people, rejoicing in plunder and slaughter; and not the least interesting part of the paper was the description of a peculiar system of female brigandage. The Koordish race were said to be remarkably handsome, and to exhibit a great variety of complexion; a dark skin, with black hair and black eyes, is the most common, but light hair and blue eyes are also to be seen.

Statistical Society, December 21.—Mr. Newmarch, F.R.S., president, in the chair. A Report on the Seventh International Statistical Congress at the Hague was read by Mr. Brown, after which Mr. R. H. Inglis Palgrave read a paper "On the House Accommodation of England and Wales." Mr. Palgrave commenced by stating that the population of England is now probably better housed than at the commencement of the century. The average number of inhabitants to a house has slightly diminished since 1801. Mr. Palgrave continued to point out that, covered by a general average, which appeared to show ample accommodation, were great inequalities. The information obtained in the English census inquiries scarcely gives the means of tracing the subject further; but the last census in Scotland showed that one-third of the population lived each family in dwellings of only one room; another third in dwellings of two rooms; only the remaining third being lodged with comfort and decency. Mr. Palgrave showed by an analysis of Mr. Dudley Baxter's calculations, that the lowest section of the population in England was nearly twice as closely packed as the general average, in dwellings more than proportionately inferior; and by a reference to the Report on the Employment of Children and Women in Agriculture, that the condition of some rural districts apparently well provided for was scarcely superior to that of Scotland. Mr. Palgrave concluded by proposing that the census inquiry for 1871 should include more details on the house accommodation of England, Wales, and Scotland, thus to ascertain present deficiencies, and to assist those who desire to remedy the evils arising therefrom. The following gentlemen were elected Fellows, viz.:—Sir Massey Lopes, Bart., M.P., Hon. H. N. D. Beyts, Dr. Macaulay, Messrs. J. O. Chadwick, A. H. Smee, C. Inglis, M.D., Hammond Chubb, S. Ingall, and James M. Davies.

Institute of Actuaries, December 21.—Mr. S. Brown, president, in the chair. The following gentlemen were elected members, viz.:—Fellows, Messrs. Cornelius Walford and Joseph J. Dymond; and Associates, Messrs. A. C. Waters, Ainslie, Talon, E. J. Sims, jun., Henry Jeula, James D. Hobson, J. Ashton, J. H. Elder, and Joseph Burne. Mr. J. B. Sprague, M.A., read a paper "On the rate of mortality prevailing among assured lives, as influenced by the length of time for which they have been assured."

Edinburgh

Royal Society of Edinburgh, December 20.—Professor Kelland, president, in the chair. The Keith Prize for the biennial period ending May 1869 having been awarded by the Council to Professor P. G. Tait, for his paper "On the Rotation of a Rigid Body about a Fixed Point," the medal was formally delivered to him, after which Professor Kelland, in making the presentation, said he had great pleasure in accompanying it with the sum of £57 0s. 10d. He briefly referred to the manner in which Professor Tait was applying the method of quaternions, and mentioned that he was now putting on a more solid basis what they might call the mechanical sciences. On every account Professor Tait was entitled to the honour which had been conferred upon him, and he had no hesitation in saying that this was only the first of a series of successes.—Mr. Archd. Geikie read a paper "On the Geological Structure of some Alpine Lake Basins." In this paper the author reviewed the arguments which had been adduced by the geologists of Switzerland to prove that the great lakes of that country are essential parts of the architecture of the Alps. He stated that this view was untenable, for the lakes, instead of coinciding with the foldings and fractures of the rocks, ran directly across them. He entered in some detail into the geological structure of several of the Alpine lakes, particularly of the Lake of the Four Cantons, with the view of showing that between the contortions and dislocations of the rocks and the trend of the lake there is no ascertained connection. By a series of diagrams he pointed out how vast an amount of rock had been removed from the site of the lake and the adjacent mountains, and that it was physically impossible that any remnant of the original surface at the time when the rocks were folded could now remain. Particular attention was called to the fact that the greatest of the known dislocations of the Alps—the fracture which has brought down the miocene against the older tertiary and secondary rocks—has not given rise to lakes and valleys, but actually crosses them, as at the lakes of Geneva, Thun, and Lucerne, and in the valleys of the Rhine and Linth. After combating the explanation by which the lakes are referred to general and special movements of subsidence, the author dwelt upon the intimate connection between the Alpine lakes and the innumerable rock basins of the rest of the northern hemisphere. This connection, he said, could hardly be accidental. It pointed to some general cause which had been at work during a recent geological period, and he could not doubt but that this general cause was the thick mantle of ice which, from independent evidence, can be shown to have enveloped a great part of Europe and North America. The idea of the erosion of lake basins by the grinding power of land ice had been first propounded by Professor Ramsay, and there seemed every reason to believe that this view would come eventually to be accepted even by the geologists of Switzerland. — Professor Turner read a preliminary notice of the great finner whale recently stranded at Longniddry. It was so seldom that one of these large whales found its way to our very doors, and there were still so many unsolved problems to be worked out in connection with the structure and classification of the larger cetacea, that he gladly availed himself of the arrival of the rare visitor to devote such time as he could spare to the study of the huge creature. The length of the animal, he said, measured from the tip of the lower jaw to the end of the tail, 78 feet 9 inches. The girth of the body, immediately behind the flipper, was 45 feet. Its girth, in line with the oval orifice, was 28 feet, whilst around the root of the tail it was only 7 feet 6 inches. The inner surface of the lower jaw close to its upper edge and on the border was concave, and sloped inwards so as to admit the edge of the upper jaw within it. The length from the angle of the mouth to the top of the lower jaw, along the curved border, was 21 feet 8 inches. The dorsum of the upper jaw was not arched in the antero posterior direction. It sloped gently upwards and backwards to the blow holes, from which a low but readily recognised median ridge passed forwards on the back, gradually subsiding some distance behind its tip. On each side of this ridge was a shallow concavity immediately in front of the blow holes, the ridge bifurcated and the forks passed backwards, enclosing the nostrils for several inches, and then subsided. The outer borders of the upper jaw were not straight, but extended forward from the angle of the mouth for some distance in a gentle curve, and then rapidly converging in front formed a somewhat pointed tip. Their rounded palatal edges fitted within the arch of the lower jaw. The transverse diameter of the upper jaw over its dorsum between the angles of the mouth was 13 feet 3 inches. From the blow holes the outline of the back, curved upwards and backwards, was uniformly smooth and rounded, and for a considerable distance presented no dorsal mesial ridge. From the tip of the lower jaw to the anterior border of the dorsal fin, the measurement was 59 feet 3 inches. Behind the dorsal fin the sides of the animal sloped rapidly downwards to the ventral surface, so that the dorsal and ventral mesial lines were clearly marked, and the sides tapered off to the tail. The ventral surface of the throat, and the sides and ventral surface of the chest and belly, were marked by numerous longitudinal ridges and furrows. When he first saw the animal, the furrows separating the ridges were not more than from $\frac{1}{4}$ to $\frac{3}{4}$ of an inch broad, whilst the ridges themselves were in many places 4 inches in breadth; but as the body began to swell by the formation of gas from decomposition, the furrows were opened up, became wider and shallower, and the ridges underwent a corresponding diminution in breadth. The flipper projected from the side of the body thirty-one feet four inches behind the top of the lower jaw, and fourteen feet behind the angle of the mouth. It curved outwards and inwards, terminating in a free, pointed end. The distance between the two flippers, measured over the back between the anterior borders of their roots, was eighteen feet six inches. On the dorsum of the beak and of the cranium, on the back of the body, and for some distance down its sides, the colour was dark steel, amounting in some sights almost to black. On a line with the pectoral flipper the sides were mottled with white, and on the ventral surface irregular, and in some cases large patches of silver grey or whitish colour were seen. The dorsal fin was steel grey or black, except near its posterior border, where it was a shade lighter and streaked with black lines. The anterior of the lobes of the tail, its upper surface near the root and for the anterior two-thirds, were black. The upper surface of the flipper was steel grey, mottled with white at the root, at the tip along its posterior or internal border and on the under surface white patches were seen, on the upper surface near the tip, and here they were streaked with black lines running in the long axis of the flipper. White patches also extended from the root of the flipper to the adjacent parts of the sides of the animal. The outside of the lower jaw was black, whilst the inside was streaked with grey and brown. The tongue of the whale was of enormous size. The dorsum was comparatively smooth in front, but at the posterior part it was elevated into hillocks, which were separated by deep furrows. The baleen had a deep black colour, and consisted on each side of the plates which projected from the palate into the cavity of the mouth. The plates were arranged in rows—370 were counted on each side—which lay somewhat obliquely across the palate, extending from near the base of the great mesial palatal ridge to the outer edge of the palate. The plates diminished in size so much that at the tip, where the two sets of baleen became continuous, they were merely stiff bristles. He was happy to state, however, that the skeleton had been secured by the directors of the Museum of Science and Art in this city, who had granted him permission to examine it as soon as it was in a fit state. Prof. M'Donald gave it as his opinion that the whale which stranded at Longniddry was a water-breathing animal, and not an air-breathing animal.—The other paper read was "On the Aggregation in the Dublin Lying-in Hospital."

MILAN

Royal Lombardian Institute, November 11.—Professor Schiaparelli communicated a note upon a recent pamphlet by Signor Gaetano Baratta, proposing a method for the geometrical trisection of any given angle. He showed by a table of measurements that the first angle obtained by M. Baratta's rule is always greater than one-third of the primary angle.—Professor Emilio Villari presented a memoir on the electro-motor force of palladium in gas batteries. The author was led by the consideration of the great attractive force of palladium for hydrogen, and the fact that the hydrogen thus held by palladium possesses great chemical activity, to apply it to the construction of gas batteries. He described the mode in which he constructed his batteries and the experiments performed with them, which showed very complex actions, but proved that a palladium-element has a greater electro-motor force than one of Grove's gas-elements, because hydrogen in contact with palladium is considerably more oxydisable than hydrogen in contact with platinum. This electromotor force is still further increased if the palladium which is in contact with oxygen (*i.e.*, the positive electrode) is oxydised.—A new determination of the orbit of Clytie (asteroid 73), with ephemerides, by Signor Giovanni Celoria, was communicated by Professor Schiaparelli.

MONTREAL

Natural History Society, November 29.—Principal Dawson in the chair. Mr. Billings read a paper on the genus *Scolithus*, and some allied Fossils. The fossils known under the names of *Scolithus* and *Arenicolites* were described as consisting of cylindrical or rod-like bodies, which penetrate the layers of sandstone perpendicularly downwards, to a distance varying from a few lines to two or three feet. There are several varieties, the most common of which has the rods from one-twelfth to one-fourth of an inch in diameter; in another more rare form they have at the surface of the beds a wide trumpet-shaped expansion, two or three inches across, but taper to a point below, where they are, in general, more or less curved. Under certain circumstances, they can be entirely separated from the rock, and then present the appearance of simple cylindrical or conical rods of sandstone with no internal structure. All the varieties are more or less distinctly marked by a series of oblique annulations—a character which Mr. Billings thought to be of importance, as it seemed to show they were all members of one family of organisms. So long as these fossils were only known by specimens exhibiting no internal structure, it was impossible to decide to which division of the animal or vegetable kingdom they belonged. The Geological Survey had, however, ascertained that the Potsdam formation included a considerable deposit of limestone, in which the same fossil forms were found, with the internal structure beautifully preserved. By these it was proved that they were not the casts of worm-burrows, but sponges. Mr. Billings believed that these ancient sponges, or at least many of them, lived in the sand or soft ooze of the ocean's bottom, with their sometimes wide and trumpet-shaped mouths either even with or a little elevated above the surface. During the discussion that followed the reading of the paper, Dr. Dawson said that if Mr. Billings was right, it would appear that in the seas of the earlier ages protozoic life had the preponderance. In reply to a question by Mr. Whiteaves, Mr. Billings said that siliceous spiculæ were found in great abundance in association with these sponges. They were generally of an elongated pyriform shape (the "acerate" form of Bowerbank). He supposed they were originally calcareous, but had become siliceous during the progress of fossilisation.—The next communication was from Dr. Carpenter upon "Different modes of Computing Sanitary Statistics, with special reference to the opinions of Mr. Andrew A. Watt." Upon this subject, which related exclusively to the statistics of population of the city of Montreal, there was an animated discussion.

Norwich

Naturalists' Society, November 30.—The Rev. J. Crompton, the president, in the chair. Mr. Southwell read a long and interesting paper "On the Flight of Birds." The seeming impossibility of a heavy body supporting itself in mid-air, gliding along, changing its direction at will, apparently violating all the known forces of nature, is sufficiently astonishing to attract the attention and engage the researches of scientific men; and yet, till of late, the subject has been neglected, or the theories formed to account for so remarkable a phenomenon have been altogether erroneous. The great stumbling-block to the arrival at the truth seems to have been the very natural idea that buoyancy was the first essential to flight, whereas it is now shown, that so far from being an essential, it is an actual impediment. Hunter discovered the presence of air-cells in the bones and dispersed over various parts of the bird's body, and it was believed that by this means heated air was used to render them lighter, and that it was possible by thus inflating the body to increase the bulk, at the same time decreasing the weight; forgetting that additional bulk without a corresponding increase of weight would but enlarge the surface presented to atmospheric resistance, thereby rendering the too buoyant body of the bird the sport of every wind that blows. Sir Charles Bell follows up this idea of excessive lightness; but Captain Hutton, in a paper on "The Birds inhabiting the Southern Ocean," shows that in order to bring the specific gravity of the albatross to that of the atmosphere, the air-cells in its body should contain 1,820 cubic feet of air heated to 108 degs.—equal to a sphere of more than 15 feet in diameter; or, in other words, they must be 1,200 times the size of the body itself, "which," he adds, "would give it, when flying, an aldermanic appearance which I have never observed." It is obvious, therefore, that the air-cells are not intended to aid the bird in flight by rendering it lighter than the air itself. After referring to the opinions of Sir Charles Bell, Mr. Southwell gave an account of the principles enunciated in France by M. de Lucy, who has shown that three great properties are absolutely essential in all winged animals—(1) weight, or the force of gravity; (2) surface, or the area presented to atmospheric resistance; and (3) force, or the power of projection. Without weight the object might float, but it could never fly, there would be no resisting force to form a fulcrum to its movements, and it would, in fact, be part of the atmosphere and subject to it, wafted hither and thither without the power of resisting. The bird being elevated in the air, possesses, in virtue of its weight, a force always exerting itself in a downward direction, thereby producing motion, which, if it has the power to control, will prove the mainspring of its flight. In order to counteract this downward motion, surface is called into request. The expanded wing is presented to a column of air perpendicular to itself, and a new law of nature comes into operation—that of atmospheric resistance. This is not sufficient to counteract the force of gravity without some mechanical action on the part of the bird, but it would in a great measure break the force of the fall, causing it to descend in a series of zigzags, as a sheet of paper falls from a balloon. We should expect to find the surface increase in proportion to the weight of the animal; but, strange to say, it has been shown by M. de Lucy that the extent of surface is always in an inverse ratio to the weight of the winged animal. The heavier the animal, the smaller its wing surface, referred to a fixed standard. This is shown remarkably in flying insects; the body is very light, but the wing surface is enormous. The bird would soon be brought down from mid-air but for the muscular power of depressing the expanded wing forcibly and rapidly so as to cause the elastic column of the air beneath to rebound with sufficient force to destroy the remaining effects of gravity and so to equalize all the forces as to leave the bird ready to pursue its course at will. The most striking thing about the skeleton of a bird is its great lightness combined with strength. By a beautiful arrangement, the greatest power is given to the wings. The front part of the wing, that first presented to the air in forward flight, is stiff and unyielding, well adapted for cutting its way through the air; the other feathers become weaker and more pliable as they are placed nearer to the body of the bird. The feathers, which are divided into two portions by a nearly central shaft, overlap each other, the anterior web, which is the strongest and stiffest, being uppermost. When the down stroke is delivered, the wing presents to the air an impenetrable and unyielding surface, but when the corresponding up stroke is made, the yielding posterior web of each feather becomes depressed by the resistance of the air above, thus separating the feathers so as to allow of the free passage of the air; by this means giving the maximum amount of force to the down stroke, which would otherwise be neutralised by the resistance of the up stroke. But this is not all; the under surface of the wing is more or less concave, while the upper surface is convex. It is obvious, therefore, that when the up stroke is made, the air will rush off and through the wing in all directions, but when the motion of the wing is reversed, the air will be gathered up in its hollow, and the resistance immensely increased. By a wonderful contrivance, the same stroke which elevates the bird gives it a forward motion also. Mr. Southwell then gave an elaborate description of the mode in which forward motion is effected, from the Duke of Argyll's work, "The Reign of Law." Those birds with very long and pointed wings possess the greatest powers of flight; as, for instance, the sharp-winged martin for speed, and the long-winged albatross for both speed and endurance. The power of turning in flight appears to be the result of an involuntary effort, as we turn or incline to the left or right in walking. It is a matter of considerable difficulty to obtain reliable data as to the actual velocity with which birds travel through the air. The flight of a hawk, when its powers are fully exerted, has been calculated at 150 miles an hour; the usual flight of the eider duck at the rate of 90 miles an hour. Audubon estimates the flight of the American passenger pigeon at a mile a minute, and the carrier pigeon to possess, probably, an average of 50 or 60 miles in a long flight, although over short distances, as when pursued by a hawk, its speed is much greater. The flight of rooks "going home to bed with full stomachs," and taking it easy, Major Holland estimates at about 26 to 30 miles an hour; the speed of the albatross whilst coursing in company with a ship, he reckons at about 90 miles an hour. The flight of other birds, such as the swallow, the eagle, and the peregrine falcon, has been estimated as of much greater speed. The power of passing with ease and rapidity over long distances is of vast importance to birds living in communities. Rooks, for instance, would soon exhaust the supply of food in their own neighbourhood. Mr. Stevenson is satisfied that the guillemots and gulls seen feeding in Yarmouth and Lowestoft Roads in summer, come from the great nesting-places on the Yorkshire coast; and Mr. Yarrel states, on the authority of Dr. Jenner and the Rev. N. Thornbury, that the domestic pigeons about the Hague "make daily marauding excursions at certain seasons of the year to the opposite shore of Norfolk, to feed on vetches—a distance of forty leagues." Mr. Southwell quoted many instances of the extraordinary power of birds to endure protracted flights; and concluded by saying that man with all his boasted skill has not been able to construct a machine to enable him to navigate the air, and, even with the bird before his eyes, he has failed to learn its lesson. In the discussion which ensued, Mr. Southwell said he hoped his paper would attract attention to the subject of the flight of birds, as very little was known about it; and the very fact that in modern days men attributed the powers of flight in birds to the air-cells being filled with hot air, showed how little the principles of flight must have been considered.

Paris

Academy of Sciences, December 20.—M. E. Becquerel presented a note by M. J. M. Gaugain on the electromotive forces developed by platinum in contact with various liquids. The author stated that when two platinum electrodes, *not platinised*, have remained in an acidulated liquid until they furnish no sensible current, if one of them be washed in distilled water and dried with blotting paper, it becomes negative on being again placed in the liquid. The opposite effect is produced with solution of potash. The effect in the latter case is much greater when the electrodes are platinised. The author ascribed this phenomenon to a modification of the electrodes consisting in a superficial adherence set up between the platinum and the acid or alkaline substance. He also remarked upon the difference of function in platinised and non-platinised electrodes, and stated that with these substances as opposite electrodes an electromotive force, equal to more than one-fourth of that of a Daniell's couple, is at first developed, but that this gradually diminished. This was ascribed by him to the slow modification of the electrodes in opposite directions. According to the author, the modification in question takes some time for its production, but it is also long persistent; and he indicated that this property of platinum electrodes may be applied to the determination of the acid or alkaline nature of liquids, even when these are so dilute as to have no action upon test-papers.—M. Peligot read a note "On the presence of potash and the absence of soda in most plants." He maintained, as on former occasions, that soda is not necessary for the nutrition of plants, and cited experiments made with potatoes cultivated close to and far from the sea, which showed no difference of constituents; soda was always absent. M. Boussingault remarked upon this communication that he had already shown, by analysis, that soda was in many cases far inferior in importance to potash, but he thought the question was especially a geological one, the composition of the ground appearing to be of much importance. M. Payne considered that spectrum analysis should be made use of in this investigation.—A discussion was raised by M. Bertrand on M. Carton's note for the demonstration of the proposition that the three angles of a triangle cannot be less than two right angles. M. Bertrand explained M. Carton's proposed demonstration.—M. Faye called attention to a passage in Genesis, in which mules are mentioned as existing in the time of Abraham, and suggested that where there were mules the horse must have been known. MM. Roulin and Milne-Edwards remarked that the passage cited by M. Faye probably related to the Hemiornis.—The following papers were also communicated:—A note by M. Bulliani on the Constitution of the Ovum in the *Sacculinæ*; a note showing that œdema does not always result from the mere ligature of vessels, but that this must be accompanied by paralysis of the vaso-motor nerves, presented by M. Claude Bernard on the part of one of his pupils; a second note by M. Perizeux on the Secular Acceleration of the Movement of the Moon; a note on the Modifications produced in Skins by the operation of Tanning, presented by M. Boussingault on the part of one of his pupils; and a note by M. Blaserga on the Graduation of Galvanometers.

PRAGUE

National Museum of Bohemia, Natural Sciences Section, Nov. 20.—Prof. T. Krejci gave a *résumé* of his researches on the Permian strata at the foot of the Riesengebirge, on the northern frontier of Bohemia. The most interesting district is that near Schwadowitz. The Permian strata and the cretaceous grit here form a crest about 2,000 feet in height, the Faltengebirge, which fills up the space between the two masses of the Riesengebirge and the Adlergebirge. Its elevation is attributable to an extensive fault situated at its southern foot; this same fault having occasioned the denudation of the coal strata of Schwadowitz which have been actively worked for some years past. The latter belong partly to the carboniferous formation, partly to the Permian, which possess a good number of species in common, just as in the basin of Schlan, near Prague, thus indicating a gradual transition from the one of these formations to the other. To the south of the Schwadowitz fault extends an abruptly-elevated ridge of Permian and cretaceous grit, the former of which is in reality the margin of an ancient fjord of the cretaceous sea running up (from the direction of Hronar) far into the Permian strata. Similar cretaceous fjords are found in the primitive strata near Czaslaw, in the centre of Bohemia, and at Kieslingswalde, in Silesia. At the northern foot of the Faltengebirge, near Radoventz, there is also a deposit of coal supposed for a long time to be carboniferous, but now acknowledged to be Permian.—M. O. Feistmantel reported on the fossil plants of Schwadowitz collected by himself and M. Krejci, in 1869. This deposit yields in point of richness to that of Radnitz: nevertheless, M. Feistmantel has discovered among nearly 2,000 specimens forty-eight species, only one of which (from this mine) was known to M. Ettingshausen. These remains are arranged in three zones. The lowest, that of the pure schist, contains Pterideæ (*Lonchopteris, Alepthopteris, Neuropteris, Sphenopteris, Adiantites, Cyatherites*), and Equisetaceæ (*Calamites, Asterophyllites, Annularia, Sphenophyllum*). The second zone, that of the black schist, contains Lycopodiaceæ (*Lepidodendron, Lepidostrobus, Lycopodites, Sagenaria*), Nöggerathiœ (*Cordaites, Noggerathia*), and Sigillariæ (*Sigillaria, Stigmaria*). The third, that of coal, contains only Sigillaria and Stigmaria. At Radganice, where fossil-trunks of Araucaria in the red grit were the only remains of plants heretofore observed, M. Feistmantel obtained from the Permian coal eleven species of the genera *Annularia, Asterophyllites, Sphenophyllum, Alettsopteris, Cyatherites, Calamites*, and *Stigmaria*. A fine specimen from this locality shows that *Huttonia spicata* is the fruit of *Calamites Suckowi*, and the constant presence of Stigmaria without Sigillaria is a strong argument against the received doctrine that Stigmaria is the root of Sigillaria.

November 24.—Prof. J. Blazek demonstrated, by an elegant method, and without making use of the higher calculus, a series of theorems relating to *polyhedra maxima* inscribed in an ellipsoid of three axes. The latter being considered as a sphere distorted according to certain laws, the author demonstrates that the *corpora maxima* inscribed in the sphere are distorted according to the same laws, and that this likewise holds good for the *corpora maxima* of the derivative ellipsoid.—M. T. Palacky explained his views of the botanical geography of Asia. M. Grisebach has recently divided Asia into four botanical provinces—Western, or that of the steppes; Eastern, or Chinese; Boreal, or Siberian; and Southern, or that of India. M. Palacky only admits two provinces, the one Southern, the other Boreal, including in the latter the whole of Asia beyond the Himalayas, because the first three provinces of M. Grisebach do not appear to him to differ more from one another in regard to their flora than the sub-provinces of each do. The author lays special stress upon the tropical species inhabiting China—where they are not arrested by steppes—as far as Pekin, and even as far as the Amoor. According to him the existing flora of Central Asia is an invasion of the Mediterranean flora, which took place after the elevation of the Turcoman plateau in the place of the ancient post-tertiary sea between Europe and Asia. The principal obstacle in the way of researches connected with botanical geography is the diversity of the views adopted by various botanists; one species of Hooker, Wallich, &c., being at least equivalent to twenty-five species of Maximowicz, Ruprecht, and most of the German botanists.

ON THE LABOURING FORCE OF THE HUMAN HEART

THERE is no organ in our bodies that has a more important influence upon health, at all ages of our lives, than the heart, whose rhythm and force are governed by laws of nerve-force, of which we are at present almost totally ignorant. Regarded, however, from a mechanical point of view, as a hydraulic pumping machine, our knowledge of the heart is more accurate, and may yet lead the way to greater knowledge of the physiological action of this vital organ.

I propose, in the present communication, to give an estimate of the daily labouring force of the human heart, and to compare it with that of other muscles, such as those used in rowing or climbing, reserving for a future communication the proof of the data to be now employed.

The heart, regarded as a pumping machine, consists of two muscular bags (*ventricles*), one of which drives the blood through the lungs, and the other through the entire body. This blood is forced, by a pumping action, repeated seventy-five times each minute, through both lungs and body, and experiences in each case a resistance which is measured by the hydrostatical pressure of the blood in the pulmonary artery and aorta. The resistance offered to the circulation of the blood, by the capillary vessels of the lungs and body, is different; but the total quantity of blood that passes through the lungs and body in a given time, must be the same; from which it follows, that the resistance offered by the capillaries must be in the proportion of the hydrostatical pressure in the great arteries leading from the ventricles of the heart. If, therefore we knew that pressure for one side of the heart, and the relative forces of the two ventricles in contracting, we should know the entire resistance overcome by the heart at each of its beats.

If, in addition to the hydrostatical pressure in one ventricle, and its ratio to that in the other ventricle, we knew also the quantity of blood forced out of each ventricle against this pressure, we should have all the elements necessary to calculate the labouring force of the heart, as will be presently shown.

I demand, therefore, that my reader shall grant me, provisionally, the following postulates, which are necessarily three in number :—

I. That three ounces of blood are driven from each ventricle at each stroke of the heart.

II. That the hydrostatical pressure in the left ventricle and aorta, against which the blood is forced out, amounts to a column of blood 9·923 feet in vertical height.

III. That the muscular force of the left ventricle, in contracting, bears to that of the right ventricle the proportion of 13 to 5.

With these postulates granted, we may now proceed to calculate the daily labouring force of the heart as follows. At every stroke of the heart, three ounces of blood are forced out of the left ventricle against a pressure of a column of blood 9·923 feet in height. The work done, therefore, at each stroke is equivalent to lifting three ounces through 9·923 feet. This work is repeated 75 times in each minute, and there are 60×24 minutes in the day. Hence, the daily work of the left ventricle of the human heart is $3 \times 9·923 \times 75 \times 60 \times 24$ ounces lifted through one foot; or, since there are 16 ounces in the pound, and 2,240lbs. in the ton, the work done by the left ventricle of the heart in one day is $\frac{3 \times 9·923 \times 75 \times 60 \times 24}{16 \times 2,240}$ tons lifted through one foot. Multiplying and dividing out this quantity, we find the daily work of the left ventricle is 89·706 foot-tons. The work done by the right ventricle is five-thirteenths of this quantity (post. III.); the daily work of the right ventricle is therefore 34·502 foot-tons. Adding these two quantities together, we find for the total daily work of the human heart 124·208 tons lifted through one foot.

It is not easy for persons unaccustomed to these calculations to appreciate quickly the enormous amount of labouring force denoted by the preceding result; but in order to facilitate this appreciation, I shall compare it with the following descriptions of labour :—

1. The daily labour of a working man.
2. The work done by an oarsman in an eight-oar boat-race.
3. The work done by locomotive engines, or animals climbing a height.

1. The daily labour of a working man, deduced from various kinds of labour, from observations spread over many months, is found to be equivalent to 354 tons lifted through one foot, during the ten hours that usually constitute the day's work. This amount of work is less than three times the work done by a single heart, beating day and night for 24 hours: thus, three old women sitting beside the fire, alternately spinning and sleeping, do more work, by the constant beating of their hearts, than can be done in a day by the youngest and strongest "navvy."

2. If an Oxford eight-oar boat be propelled through the water at the rate of one knot in seven minutes, the resistance offered by the water may be estimated at 81·36 lbs. by calculation, or at 74·15 lbs. by actual observation. From this result, and from the fact that 575 ounces of muscle are employed by each of the eight oarsmen, we can calculate that 15 foot-pounds of work are expended by each ounce of muscle during each minute of work.

No labour that we can undertake is regarded as more severe than that of the muscles employed during a boat-race; and yet this labour, severe as it is, is only three-fourths of that exerted day and night during life by each of our hearts.

The average weight of the human heart, which increases with age (for obvious reasons), may be estimated from the following tables :—

	Average oz.
1. Meckel	10·0
2. Cruveilhier	7·5
3. Bouilland	8·4
4. Lobstein	9·5
5. Boyd (æt. 30—40)	10·4
6. Boyd (æt. 40—50)	10·5
Mean	9·39

From this weight, and the work done by the heart in one day (124 foot-tons), we can calculate the work done by each ounce of the heart in one minute, as follows :—

Work done by the human heart, in foot-pounds per ounce per minute, $\frac{124·208 \times 2240}{9·39 \times 24 \times 60} = 20·576$ foot-pounds.

This amount of work exceeds the work done by the muscles during a boat-race (as already stated) in the proportion of 20 to 15, or of 4 to 3.

3. There is yet another mode of stating the wonderful energy of the human heart. Let us suppose that the heart expends its entire force in lifting its own weight vertically; then the total height through which it could lift itself in one hour is thus found, by reducing the daily work done in foot-tons (124·208) to the hourly work done in foot-ounces, and dividing the result by the weight of the heart in ounces:—

Height through which the human heart could raise its own weight in one hour $= \frac{124·208 \times 2240 \times 16}{24 \times 9·39} = 19754$ ft.

An active pedestrian can climb from Zermatt to the top of Mont Rosa, 9,000 feet, in nine hours; or can lift his own body at the rate of 1,000 feet per hour, which is only one-twentieth part of the energy of the heart.

When the railway was constructed from Trieste to Vienna, a prize was offered for the locomotive Alp engine that could lift its own weight through the greatest height in one hour. The prize locomotive was the "Bavaria," which lifted herself through 2,700 feet in one hour; the greatest feat as yet accomplished on steep gradients. This result, remarkable as it is, reaches only one-eighth part of the energy of the human heart.

From whatever mechanical point of view, therefore, we regard the human heart, it is entitled to be considered as the most wonderful mechanism we are acquainted with. Its energy equals one-third of the total daily force of all the muscles of a strong man; it exceeds by one-third the labour of the muscles in a boat-race, estimated by equal weights of muscle; and it is twenty times the force of the muscles used in climbing, and eight times the force of the most powerful engine invented as yet by the art of man.

No reflecting mind can avoid recognising in its perfection, and regarding with reverential awe, the Divine skill that has constructed it.

SAMUEL HAUGHTON

THE SCIENCE OF LANGUAGE

Darwinism tested by the Science of Language. Translated from the German of Professor August Schleicher, by Dr. Alex. V. W. Bikkers. (London: J. C. Hotten, 1869.)

IT is not very creditable to the students of the Science of Language that there should have been among them so much wrangling as to whether that science is to be treated as one of the natural or as one of the historical sciences. They, if any one, ought to have seen that they were playing with language, or rather that language was playing with them, and that unless a proper definition is first given of what is meant by nature and by natural science, the pleading for and against the admission of the science of language to the circle of the natural sciences may be carried on *ad infinitum.* It is, of course, open to anybody so to define the meaning of nature as to exclude human nature, and so to narrow the sphere of the natural sciences as to leave no place for the science of language. It is possible also so to interpret the meaning of growth that it becomes inapplicable alike to the gradual formation of the earth's crust, and to the slow accumulation of the *humus* of language. Let the definitions of these terms be plainly laid down, and the controversy, if it will not cease at once, will at all events become more fruitful. It will then turn on the legitimate definition of such terms as nature and mind, necessity and free-will, and it will have to be determined by philosophers rather than by scholars.

Unless appearances deceive us, it is not the tendency of modern philosophy to isolate human nature and to separate it by impassable barriers from nature at large, but rather to discover the bridges which lead from one bank to the other, and to lay bare the hidden foundations which, deep beneath the surface, connect the two opposite shores. It is, in fact, easy to see that the old mediæval discussions on necessity and free-will are turning up again in our own time, though slightly disguised, in the discussions on the proper place which man holds in the realm of nature; nay, that the same antinomies have been at the root of the controversy from the days when Greek philosophers maintained that language existed either *φύσει* or *θέσει*, to our own days, when scholars range themselves in two hostile camps, claiming for the Science of Language a place either among the physical or the historical branches of knowledge.

It is by supplying a new point of view for the consideration of these world-old problems, that Darwin's book "On the Origin of Species" has exercised an influence far beyond the sphere for which it was originally intended. The two technical terms of "Natural Selection" and "Struggle for Life," which are in reality but two aspects of the same process, are the very categories which were wanted to enable us to grasp by one effort of thought the reciprocal action of the one on the many and of the many on the one; the mutual dependence of individuals, species, and genus; or, from another point of view, the inevitable limitation of spontaneous action by the controlling influences of social life. I may be allowed to repeat what I said on a former occasion:—"Who has thought about the changes which are brought about, apparently by the exertions of individuals, but for the accomplishment of which, nevertheless, individual exertions would seem to be totally unavailing, without feeling the want of a word—that is to say, in reality, of an idea—to comprehend the influence of individuals on the world at large, and of the world at large on individuals; an idea that should explain the failure of Huss in reforming the Church, and the success of Luther; the defeat of Pitt in carrying parliamentary reform, and the success of Russell? How are we to express that historical process in which the individual seems to be a free agent, and yet is the slave of the masses whom he wants to influence; in which the masses seem irresistible, and are yet swayed by the pen of an unknown writer? Or, to descend to smaller matters, how does a poet become popular? How does a new style of art or architecture prevail? How, again, does fashion change?—how does what seemed absurd last year become recognised in this, and what is admired in this become ridiculous in the next season? Or take language itself. How is it that a new word, such as 'to shunt,' or a new pronunciation, such as '*gold*' instead of '*goold*,' is sometimes accepted, while at other times the last words newly coined or newly revived by our best writers are completely ignored or fall dead? We want an idea that is to exclude caprice as well as necessity—that is, to include individual exertion as well as general co-operation—an idea applicable neither to the unconscious building of bees, nor to the conscious architecture of human beings, yet combining within itself both these operations, and raising them to a new and higher conception. You will guess both the idea and the word, if I add that it is likewise to explain the extinction of fossil kingdoms and the origin of new species:—it is the idea of 'Natural Selection' that was wanted, and being wanted it was found, and being found it was named. It is a new category, a new engine of thought; and if naturalists are proud to affix their names to a new species which they discover, Mr. Darwin may be prouder, for his name will remain affixed to a new idea, to a new genus of thought." *

Professor Schleicher, whose recent death has left a gap in the ranks of the students of language which it will be difficult to fill, has written down the impressions which he, as a comparative philologist, received from a perusal of Mr. Darwin's work, in a letter addressed to his distinguished colleague, Professor Haeckel, of Jena. It is but a slight sketch, and it would not be fair if the English public took the measure of Professor Schleicher's powers from the translation of his pamphlet which has just been published by Dr. Bikkers, under the somewhat inappropriate title of "Darwinism tested by the Science of Language." Professor Schleicher could hardly have thought that the truth or falsehood of Mr. Darwin's theories depended on any test that can be applied to them by the Science of Language. But he thinks rightly that the genesis of species, as explained by Mr. Darwin, receives a striking illustration in the genealogical system of languages, and particularly of the Aryan and Semitic languages; and he very properly calls attention to the fact, that as this ramification of human speech took place within what may be called, if not historical, at least post-tertiary times, it may be useful as a kind of confirmation of Mr. Darwin's theory, which postulates a similar process in far more distant periods of the world's history. "We observe," he says, "during historical periods how species and genera of speech disappear, and how others extend themselves at the expense of the dead. I only remind you, by way of illustration, of the spread of the Indo-Germanic family, and the decay of the American languages. In the earlier times, when languages were still spoken by comparatively weak populations, this dying-out of forms of speech was, no doubt, of much more frequent occurrence, and, as the idioms of a higher organisation must have existed for a very long time, it follows that the pre-historic period in the life of speech must have been a much longer one than that which falls within the limits of historical record. . . . . It is very possible that many more species of speech perished during the course of that time than the number of those which have prolonged their existence up to the present day. This explains the possibility of so great an extension as, for instance, that of the Indo-Germanic, the Finnic, the Malay, and South African families, which, over a large territory, branched off into such a multitude of directions. A similar process is assumed by Mr. Darwin with regard to the animal and vegetable creation; that is, what he calls 'the struggle for life.' A multitude of organic forms had to perish in the struggle in order to make room for comparatively few favoured races."

Although this struggle for life among separate languages exhibits some analogy with the struggle for life among the more or less favoured species in the animal and vegetable kingdoms, there is this important difference that the defect and the gradual extinction of languages depend frequently on external causes, *i.e.* not on the weakness of the languages themselves, but on the weakness, physical, moral, or political, of those who speak them. A much more striking analogy, therefore, than the struggle for life among separate languages, is the struggle for life among words and grammatical forms which is constantly going on in each language. Here the better, the shorter, the easier forms are constantly gaining the upper hand, and they really owe their success to their own inherent virtue. Here, if anywhere, we can learn that what is called the process of natural selection, is at the same time, from a higher point of view, a process of rational elimination; for what seems at first sight mere accident in the dropping of old and the rising of new words, can be shown in most cases to be due to intelligible and generally valid reasons. Sometimes these reasons are purely phonetic, and those words and forms are seen to prevail which give the least trouble to the organs of pronunciation. At other times the causes are more remote. We see how certain forms of grammar which require little reflection, acquire for that very reason a decided numerical preponderance; become, in fact, what are called regular forms, while the other forms, generally the more primitive and more legitimate, dwindle away to a small minority, and are treated at last as exceptional and irregular. In the so-called dialectic growth of languages we see the struggle for life in full play, and though we cannot in every instance explain the causes of victory and defeat, we still perceive, as a general rule, that those words and those forms carry the day which for the time being seem best to answer their purpose. Why did the French use *maison*, i.e. mansion, for house? Because *casa* having dwindled down to *chez* was not sufficiently distinct in pronunciation, and because *domus* being frequently used for ecclesiastical buildings, was no longer sufficiently precise in its meaning, if applied to an ordinary house. Why do verbs in *ir*, like *finir*, form the plural *nous finissons*, instead of *nous finons?* Because the example which was set in Latin by the early formation of so-called inchoative verbs, like *durescere, florescere, implescere, gemiscere*, proved attractive, partly on account of its removing any doubts on the exact terminations of a verb, partly because of its giving a fuller body to monosyllabic verbs. Thus *finiscere* was substituted for *finire* in all tenses but the infinitive, the perfect, the future, and the conditional; and while this new species, the so-called second conjugation, was gradually being established, a few scattered remnants only survived of the former race, fossilised, petrified, or, as they are called in grammatical parlance, irregular, such as *nous venons* from *venir*, *nous partons* from *partir*, &c.

There is one point on which Professor Schleicher seems to have misapprehended the meaning of Mr. Darwin. According to him, the different species of the Aryan as well as of the Semitic languages presuppose each a typical language from which they are genealogically

* "Lectures on the Science of Language." Second Series. Second Edition, p. 309.

derived. There was, according to him, an ancient Aryan language, not only perfect and complete in itself, but so constituted that it contained the germs of everything which we find in Sanskrit, Greek, Latin, German, Celtic, and Slavonic. Such a language may no doubt be constructed theoretically, in the same manner as out of French, Italian, Spanish, and Portuguese, some kind of Latin language might be reconstructed. But such Latin would be very different from real Latin. Historically the admission of type-languages is perfectly impossible. No one would think of deriving the ancient Greek dialects from one actually existing common language containing within itself the germs of every dialect. No one could realise a language which should be at the same time both High and Low, and yet neither High nor Low German. What kind of language could the primitive Celtic have been, if it had to combine the peculiarities of the Gadhelic and the Cymric branches? How could a common Italian language have existed, if it had to maintain and to neutralise the distinctive features of Oscan, Latin, or Umbrian speech? What applies to the dialects of each language, applies with the same force to all these languages in common, when considered themselves as dialects of Aryan speech. As we cannot derive the Greek dialects from a presupposed primitive κοινή, we should not attempt to derive the great dialects—viz. Greek, Latin, Celtic, Teutonic, and Slavonic—from a presupposed primitive Palæo-Aryan type of speech. In tracing the origin of species, whether among plants or animals, we do not begin with one perfect type of which all succeeding forms are simply modifications, but we begin with an infinite variety of attempts, out of which by the slow but incessant progress of natural selection, more and more perfect types are gradually elaborated, some of which are still further improved by artificial domestication. It is the same with languages. The natural state of language consists in unlimited dialectic variety, out of which, by incessant weeding, more and more definite forms of languages are selected, till at last by literary cultivation those highly elaborated classical languages are produced which, in spite of their beauty, are nevertheless abnormal and unnatural, and invariably die without leaving any offspring. New languages do not spring from classical parents, but draw their life and vigour from the spoken rustic and vulgar dialects. No reader of Mr. Darwin's books can fail to see that an analogous process pervades the growth of a new species of language, and of new species of animal and vegetable life. But these analogies should not be carried too far. At all events we should never allow ourselves to forget that, if we speak of languages as natural productions, and of the science of language as one of the natural sciences, what we chiefly wish to say is, that languages are not produced by the free-will of individuals, and that if they are works of art, they are works of what may be called a natural or unconscious art—an art in which the individual, though he is the agent, is not a free agent, but checked and governed from the very first breath of speech by the implied co-operation of those to whom his language is addressed, and without whose acceptance language, not being understood, would cease to be language.

There are other spheres of mental activity to which the same remark applies, but to none so much as to language. It might be said, and it has been said by high authorities, that neither in framing his codes of law, nor in settling the rules of morality, nor in believing the truths of religion, is man an entirely free agent, but that the freedom of the individual is necessarily limited by the pressure exercised by all upon all, and by the circumstances and conditions of the age in which we live. It is true, also, that the science of psychology, which forms the basis of juridical, ethical, and religious science, is imperfect unless it has its foundations in physiology. "La tendance de la physiologie moderne," as M. Claude Bernard remarks, "est donc bien caractérisée ; elle veut expliquer les autres phénomènes intellectuels au même titre que tous les autres phénomènes de la vie ; et si elle reconnait avec raison qu'il y a des lacunes plus considérables dans nos connaissances relativement aux mécanismes fonctionnels de l'intelligence, elle n'admet pas pour cela que les mécanismes soient par leur nature ni plus ni moins accessibles à notre investigation que ceux de tous les autres actes vitaux ?"

But in none of these spheres of mental activity is the freedom of the individual so completely absorbed, and all but annihilated, as in the sphere of language. Not only are the first impulses of language purely physical ; not only is the material of language entirely dependent on the physical organs, such as they are ; not only does the activity of the functional nervous centre of speech become quickly habitual, automatic, and almost instinctive, but even in its purely mental aspect, language rests from the very first on an unconscious compromise. Speech in its very nature is mutual : even a mere exclamation is nothing unless it is understood. Even now we do not speak to others as we should speak to ourselves, but speak their language rather than our own. So it was, only in an infinitely higher degree, in the first formation of speech. If we represent the individual speaker by ^{1}, and the unlimited number of his fellow-creatures by x, the conscious freedom of action which can be claimed for any individual speaker may be expressed by $^1/x$, a quantity oscillating between one divided by one, and one divided by infinity. With every generation this x becomes larger and larger, because it includes not only the present, but the more powerful influence of the past, till at last use and habit exercise the power of a tyrant,

"Quem penes arbitrium est et jus et norma loquendi,"

and whose behests we can no more think of disobeying than the laws of nature.

It is but fair to state, in conclusion, that the first suggestion of the necessity of admitting some of the so-called moral sciences to the circle of the natural sciences came, not from the students of psychology and glossology, but from the historian of the inductive sciences, who saw that the old definition of natural science was becoming too narrow, and that with a new definition the circle of physical knowledge had necessarily to be widened. Dr. Whewell wrote in 1845 :—"We have seen that biology leads us to psychology, if we choose to follow the path ; and thus the passage from the material to the immaterial has already unfolded itself at one point ; and we now perceive that there are several large provinces of speculation which concern subjects belonging to man's immaterial nature, and which are governed by the same laws as sciences altogether physical.

It is not our business to dwell on the prospects which our philosophy thus opens to our contemplation; but we may allow ourselves, in this last stage of our pilgrimage among the foundations of the physical sciences, to be cheered and animated by the ray that thus beams upon us, however dimly, from a higher and brighter region."

MAX MÜLLER

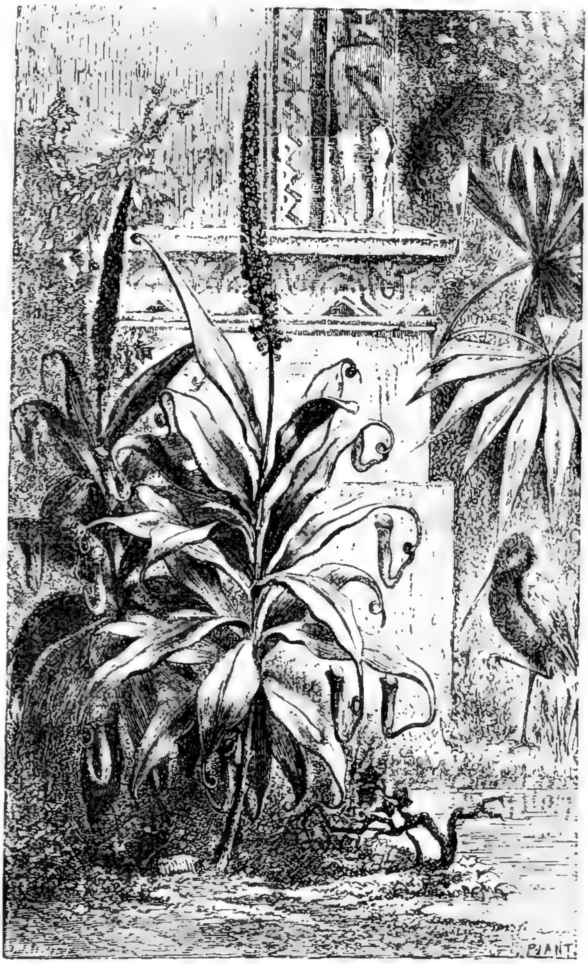
THE UNIVERSE

The Universe; or, the Infinitely Great and the Infinitely Little. By F. A. Pouchet, M.D., &c. Pp. 790, 343 engravings, 4 coloured plates. (London: Blackie and Son.)

"WHAT a charming title!" was the thought which first came to us when we saw the announcement of this splendid book. "What a terrible title!" was the thought which swiftly followed. Is it a message from some modern prophet to a people, who, having eyes, see not, and having ears, hear not; imploring them to take heed to the tale written in every character in all space, and chanted in every note by every atom, so long and so often in vain? Will it tell us of the signs written in lines of light and lines of black, which have been travelling earthward from the outermost space since the oldest time, till now unnoticed and unread? Will it speak of the oozy mother of living things, which lies and creeps and grows over the whole bottom of the ocean's depths, and comes and goes in every little stagnant pool and slimy puddle? Will it teach us of the quivering flight of atoms in every fire that burns on earth, and in the flaming ministers which rush through illimitable space; of the fairy chains which are welded when the chamber window is sculptured with the frost, and which hold in bonds the elements of the salt that is spilt; and of the giant chains which curb the comets and bind the invisible stars to us? Will it make us to know the great pulsations which shake the earth, and the little throbs which stir the tiny cells of every thing which lives and dies?

All notions of this kind were scattered to the winds when the volume came into our hands. The prophets of old were clothed in sackcloth and ashes, and those of to-day go about in black, mourning for the sins of the people; but this work is resplendent in purple and gold—a very Dives among books. And every anticipation of a prophetic wail died away when we found that the author was a Frenchman.

NEPTUNE'S CUP (*Raphidophora latera*)



PITCHER PLANT (*Nepenthes distillatoria*, Linn.)

It is just such a work as might be expected from a nimble-witted gyrating Gaul, a sort of *petit maitre* of omniscience. We remember to have heard a criticism passed on a controversial work, made up of many short, somewhat disconnected chapters, to the effect that it reminded the reader of a dog in a kennel coming out at intervals to have a short sharp bark, and then quickly going in again. "The Universe," in a somewhat similar manner, reminds us of the dissolving-views at which the lecturer goes in and out at every view. It is, in fact, a pictorial entertainment, in which M. Pouchet takes the reader, agreeably and without exertion, through all time and all space, with remarks by the way. A picture is presented and the author tells us a little about it, playing all the while (so that the affair may not be tedious) a pretty accompaniment of eloquent diction, charming fancies, and pleasing sarcasm; then another picture is put before the readers, and again another entertainment is begun and finished in like fashion. In this way the author brings before his audience something about most things, treading with a light fantastic mind over the animal and vegetable kingdoms, the formation of the globe, fossils, volcanoes, glaciers, the sun, the stars and immensity, and many other things besides; and as dissolving-views generally end, or used to end, with a chromatrope, so M. Pouchet finishes with an amusing chapter on monsters and superstitions. To every topic there is a picture. We have reproduced two of the smallest and simplest; but a very large number of them are extremely beautiful full-page drawings. And if in them the naked truth is anywhere departed from, it is only for the purpose of heightening the entertainment.

Our readers will already have seen that we regard the letter-press as subsidiary to the pictures; and as far as we can judge, that seems to be also M. Pouchet's own view. The great fault we have to find with the writing, relates to the extreme elegance of the diction. In England we generally talk of bird's nests, but M. Pouchet dwells with zest on the Nuptial Arbour of the Bower Birds; and in the same spirit we have a good deal about "the Nuptials of Plants." In the next edition we shall probably hear something about the Hymeneals of Bathybius.

It is an old question which has puzzled many generations of mothers and nurses, "whether it is better to give a child his powder in jam until he discover the deception, or to be straightforward from the beginning and make the powder go down all nasty as it is." And we may take it for granted that to the general reader simple naked scientific truths are at first as unpalatable as medicine; so that with them too the question of what the old apothecaries used to call "a vehicle" has always to be considered. This question we do not pretend to decide, however strong our own private convictions may be; but to those who range themselves on the side of jam we may recommend this volume as a most skilfully prepared, and not unwholesome confection, with not too much medicine in it. The author states in his preface that he wrote it in the hope of exciting some love of science in his readers, and the researches which have made his name distinguished, are evidence that he has himself a real love of science to no small degree. We can readily imagine how a mind, especially a young mind, fascinated by these beautiful pictures and interested in the lightsome narrative, should let the things grow upon him until there sprang up an actual fondness for plain scientific truth, and he came at last to think that "the medicine was food." To such, and towards such an end, we can heartily commend it.

OUR BOOK SHELF

The Origin of the Seasons. By Samuel Mossman. (Edinburgh: Blackwood & Sons. 1869.)

A PLEASANTLY written and interesting work, spoiled by being coupled with a preposterous theory. Mr. Mossman boldly attempts a difficult task. He proposes to solve a complex problem on very simple principles. Unfortunately his principles are unsound; and overlooking this, there remains the objection that they do not solve his problem. This problem is the well-known fact that in bygone ages plants existed in high latitudes—as far north as England, for example—whose analogues are now only found in the tropics. Mr. Mossman explains this very simply. The obliquity of the ecliptic is now slowly decreasing; therefore it must once have been increasing, and doubtless—though astronomy objects—there was at one time no obliquity: in those days perpetual spring reigned on the earth. But there began a series of upheavals, he says, "directed chiefly towards the northern hemisphere almost exclusively," and this hemisphere becoming overweighted, naturally began to incline. The inclination became at length perhaps twice as great as at present, or even more; but then the southern hemisphere began in its turn to be upheaved, and so checked the increase of inclination, and caused the present process of slow decrease. Mr. Mossman thinks there is nothing in this "contrary to the universal law of gravitation," an opinion which he would modify were he more familiar with that law. The want of balance he speaks of would affect precession and nutation, but not the inclination of the earth's axis. Supposing gravity were on his side, however, and we granted his extension of the tropics, he should remember that the Arctic regions would be equally extended. If he brings the northern tropic to the latitude of London, he has brought the Arctic circle to the latitude of Madrid. Tropical plants in the latitude of Paris, say, would fare ill under this arrangement.

Recherches sur la Faune de Madagascar et de ses Dépendances. Ire. Partie: Relation de Voyage. Par Francois P. L. Pollen. (Leyde: Steenhoff, 1868.)

M. POLLEN, being fond of sport, and having a mind to travel, after consulting Professor Schlegel, started for Madagascar, and spent there a considerable time exploring that and the neighbouring islands, having M. C. Van Dam for companion and preparer of skins, &c. He now publishes the results of his expedition, in large quarto, with profuse illustration in the form of lithographic plates. There are to be five parts to this work—(1) The account of the expedition, (2) the mammifers and birds, (3) the reptiles, (4) the fish, (5) the insects, crustacea, and molluscs. M. Pollen writes the first himself, whilst Professors Schlegel, Bleeker, Vollenhoven, Herklots, and Selys Longchamps assist in the more strictly scientific portion. At present we have only M. Pollen's account of his voyage before us, which is written in a popular style—as he says in the preface—and is as interesting as could be expected. We should suppose that M. Pollen is not himself profoundly scientific; but he has good assistance for the rest of his work.

Country Walks of a Naturalist with his Children. By Rev. W. Houghton. (London: Groombridge and Sons, 1869.)

IF the author had aimed at interesting children of a somewhat larger growth than he has had in view, we think he would have succeeded. The trivial parts of the book will hardly please boys and girls capable of understanding the more solid portions.

A PLEA FOR THE MATHEMATICIAN

II.

I MIGHT go on, were it necessary, piling instance upon instance to prove the paramount importance of the faculty of observation to the process of mathematical discovery.* Were it not unbecoming to dilate on one's personal experience, I could tell a story of almost romantic interest about my own latest researches in a field where Geometry, Algebra, and the Theory of Numbers melt in a surprising manner into one another, like sunset tints or the colours of the dying dolphin, "the last still loveliest" (a sketch of which has just appeared in the Proceedings of the London Mathematical Society),† which would very strikingly illustrate how much observation, divination, induction, experimental trial, and verification—causation, too (if that means, as, if it mean anything, I suppose it must, mounting from phenomena to their reasons or causes of being)—have to do with the work of the mathematician. In the face of these facts, which every analyst can vouch for out of his own knowledge and personal experience, how can it be maintained, in the words of Professor Huxley (who, in this instance, is speaking of the sciences as they are in themselves and without any reference to scholastic discipline), that Mathematics "is that study which knows nothing of observation, nothing of induction, nothing of experiment, nothing of causation"?‡

I, of course, am not so absurd as to contend that the habit of observation of external nature‖ will be best or at all cultivated by the study of mathematics, leastways as that study is at present conducted; and no one can desire more earnestly than myself to see natural and experimental science introduced into our schools as a primary and indispensable branch of education: I think that that study and mathematical culture should go on hand in hand together, and that they would greatly influence each other for their mutual good. I should rejoice to see mathematics taught with that life and animation which the presence and example of her young and buoyant sister could not fail to impart; short roads preferred to long ones; Euclid honourably shelved or buried "deeper than did ever plummet sound" out of the schoolboy's reach; morphology introduced into the elements of Algebra; projection, correlation, and motion accepted as aids to geometry; the mind of the student quickened and elevated and his faith awakened by early initiation into the ruling ideas of polarity, continuity, infinity, and familiarisation with the doctrine of the imaginary and inconceivable.

It is this living interest in the subject which is so wanting in our traditional and mediæval modes of teaching. In France, Germany, and Italy, everywhere where I have been on the Continent, mind acts direct on mind in a manner unknown to the frozen formality of our academic institutions; schools of thought and centres of real intellectual co-operation exist; the relation of master and pupil is acknowledged as a spiritual and a lifelong tie connecting successive generations of great thinkers in an unbroken chain, just as we read, in the catalogue of our French Exhibition, or of the Salon at Paris, of this man or that being the pupil of one great painter or sculptor and the master of another. When followed out in this spirit, there is no study in the world which brings into more harmonious action all the faculties of the mind than the one of which I stand here as the humble representative and advocate. There is none other which prepares so many agreeable surprises for its followers, more wonderful than the transformation scene of a pantomime, or, like this, seems to raise them, by successive steps of initiation, to higher and higher states of conscious intellectual being.

This accounts, I believe, in part for the extraordinary longevity of all the greatest masters of the Analytical art, the Dii Majores of the mathematical Pantheon. Leibnitz lived to the age of 70; Euler to 76; Lagrange to 77; Laplace to 78; Gauss to 78; Plato, the supposed inventor of the conic sections, who made mathematics his study and delight, who called them the handles or aids to philosophy, the medicine of the soul, and is said never to have let a day go by without inventing some new theorems, lived to 82; Newton, the crown and glory of his race, to 85; Archimedes, the nearest akin, probably, to Newton in genius, to 75, and might have lived on to be 100, for aught we can guess to the contrary, when he was slain by the impatient and ill-mannered sergeant sent to bring him before the Roman General, in the full vigour of his faculties, and in the very act of working out a problem; Pythagoras, in whose school, I believe, the word mathematician (used, however, in a somewhat wider than its present sense) originated, the second founder of geometry, the inventor of the matchless theorem which goes by his name, the precognizer of undoubtedly the miscalled Copernican theory, the discoverer of the regular solids and the musical canon (who stands at the very apex of this pyramid of fame), if we may accept the tradition, after spending 22 years studying in Egypt and 12 in Babylon, opened school when 56 or 57 years old in Magna Græcia, married a young wife when past 60, and died, carrying on his work with energy unspent to the last, at the age of 99. The mathematician lives long and lives young; "the wings of his soul do not early drop off, nor do its pores become clogged with the earthy particles blown from the dusty highways of vulgar life."

Some people have been found to regard all mathematics, after the 47th proposition of Euclid, as a sort of morbid secretion, to be compared only with the pearl said to be generated in the diseased oyster, or, as I have heard it described, "une excroissance maladive de l'esprit humain.

* Newton's Rule (subsequently and for the first time deduced to demonstration in No. 2 of the London Mathematical Society's Proceedings) was to all appearance, and according to the more received opinion, obtained inductively by its author. So also my reduction of Euler's problem of the Virgins (or rather one slightly more general than this) to the form of a question (or, to speak more exactly, a set of questions) in simple partitions was (strangely enough) first obtained by myself inductively, the result communicated to Prof. Cayley, and proved subsequently by each of us independently, and by perfectly distinct methods.

† Under the title of "Outline Trace of the Theory of Reducible Cyclodes."

‡ Induction and analogy are the special characteristics of modern mathematics, in which theorems have given place to theories and no truth is regarded otherwise than as a link in an infinite chain. "Omne exit in infinitum" is their favourite motto and accepted axiom. No mathematician now-a-days sets any store on the discovery of isolated theorems, except as affording hints of an unsuspected new sphere of thought, like meteorites detached from some undiscovered planetary orb of speculation. The form, as well as matter, of mathematical science, as must be the case in any true living organic science, is in a constant state of flux and the position of its centre of gravity is liable to continual change. At different periods in its history, defined with more or less accuracy, as the science of number or quantity, or extension or operation or arrangement, it appears, at present, to be passing through a phase in which the development of the notion of continuity plays the leading part. In exemplification of the generalising tendency of modern mathematics, take so simple a fact as that of two straight lines or two planes being incapable of including "a space." When analysed this statement will be found to resolve itself into the assertion that if two out of the four triads that can be formed with four points lie respectively *in directum*, the same must be true of the remaining two triads; and that if two of the five tetrads that can be formed with five points lie respectively *in plano*, the remaining three tetrads (subject to a certain obvious exception) must each do the same. This at least is one way of arriving at the notion of an unlimited rectilinear and planar scheme of points. The two statements above made, translated into the language of determinants, immediately suggest as their generalised expression my great "Homaloidal Law," which affirms that the vanishing of a certain specifiable number of minor determinants of a given order of any matrix (*i.e.* rectangular array of quantities) implies the simultaneous evanescence of all the rest of that order. I made (*inter alia*) a beautiful application of this law (which is, I believe, recorded in Mr. Spottiswoode's valuable treatise on Determinants, but where besides I know not) to the establishment of the well-known relations, wrung out with so much difficulty by Euler, between the cosines of the nine angles which two sets of rectangular ones in space make with one another. This is done by contriving a matrix such that the six known equations connecting the nine cosines taken both ways in sets of threes shall be expressed by the evanescence of six of its minors; the simultaneous evanescence of the remaining minors given by the Homaloidal Law will then be found to express the Eulerian relations in question, which are thus obtained by a simple process of inspection and reading off, without any labour whatever. The fact that such a law, containing in a latent form so much refined algebra, and capable of such interesting immediate applications, should present itself to the *observation* merely as the extended expression of the ground of the possibility of our most elementary and seemingly intuitive conceptions concerning the right line and plane, has often filled me with amazement to think of.

‖ As the prerogative of Natural Science is to cultivate a taste for observation, so that of Mathematics is, almost from the starting point, to stimulate the faculty of invention.

Others find its justification, its "raison d'être," in its being either the torch-bearer leading the way, or the handmaiden holding up the train of Physical Science; and a very clever writer in a recent magazine article, expresses his doubts whether it is, in itself, a more serious pursuit, or more worthy of interesting an intellectual human being, than the study of chess problems or Chinese puzzles.* What is it to us, they say, if the three angles of a triangle are equal to two right angles, or if every even number is, or may be, the sum of two primes,† or if every equation of an odd degree must have a real root? How dull, stale, flat and unprofitable are such and such like announcements! Much more interesting to read an account of a marriage in high life, or the details of an international boat-race. But this is like judging of architecture from being shown some of the brick and mortar, or even a quarried stone of a public building—or of painting from the colours mixed on the palette, or of music by listening to the thin and screechy sounds produced by a bow passed haphazard over the strings of a violin. The world of ideas which it discloses or illuminates, the contemplation of divine beauty and order which it induces, the harmonious connexion of its parts, the infinite hierarchy and absolute evidence of the truths with which mathematical science is concerned, these, and such like, are the surest grounds of its title to human regard, and would remain unimpaired were the plan of the universe unrolled like a map at our feet, and the mind of man qualified to take in the whole scheme of creation at a glance.

In conformity with general usage, I have used the word mathematics in the plural; but I think it would be desirable that this form of word should be reserved for the applications of the science, and that we should use mathematic in the singular number to denote the science itself, in the same way as we speak of logic, rhetoric, or (own sister to algebra‡) music. Time was when all the parts of the subject were dissevered, when algebra, geometry, and arithmetic either lived apart or kept up cold relations of acquaintance confined to occasional calls upon one another; but that is now at an end; they are drawn together and are constantly becoming more and more intimately related and connected by a thousand fresh ties, and we may confidently look forward to a time when they shall form but one body with one soul. Geometry formerly was the chief borrower from arithmetic and algebra, but it has since repaid its obligations with overflowing usury; and if I were asked to name, in one word, the pole-star round which the mathematical firmament revolves, the central idea which pervades as a hidden spirit the whole corpus of mathematical doctrine, I should point to Continuity as contained in our notions of space, and say, It is this, it is this! Space is the Grand *Continuum* from which, as from an inexhaustible reservoir, all the fertilizing ideas of modern analysis are derived; and as Brindley, the engineer, once allowed before a parliamentary committee that, in his opinion, rivers were made to feed navigable canals, I feel sometimes almost tempted to say that one principal reason for the existence of space, or at least one principal function which it discharges, is that of feeding mathematical invention. Everybody knows what a wonderful influence geometry has exercised in the hands of Cauchy, Puiseux, Riemann, and his followers Clebsch, Gordan, and others, over the very form and presentment of the modern calculus, and how it has come to pass that the tracing of curves, which was once to be regarded as a puerile amusement, or at best useful only to the architect or decorator, is now entitled to take rank as a high philosophical exercise, inasmuch as every new curve or surface, or other circumspection of space, is capable of being regarded as the synthesis and embodiment of some specific organised system of continuity.*

The early study of Euclid made me a hater of geometry, which I hope may plead my excuse if I have shocked the opinions of any in this room (and I know there are some who rank Euclid as second in sacredness to the Bible alone, and as one of the advanced outposts of the British Constitution) by the tone in which I have previously alluded to it as a school-book; and yet, in spite of this repugnance, which had become a second nature in me whenever I went far enough into any mathematical question, I found I touched, at last, a geometrical bottom; so it was, I may instance, in the purely arithmetrical theory of partitions; so, again, in one of my more recent studies the purely algebraical question of the invariantive criteria of the nature of the roots of an equation of the fifth degree; —the first inquiry landed me in a new theory of polyhedra, the latter found its perfect and only possible complete† solution in the construction of a surface of the ninth order and the sub-division of its infinite contents into three distinct natural regions.‡

Having thus expressed myself at greater length

* Is it not the same disregard of principles, the same *indifference to truth for its own sake*, which prompts the question "Where's the good of it?" in reference to speculative science, and "Where's the harm of it?" in reference to white lies and pious frauds? In my own experience I have found that the very same people who delight to put the first question are in the habit of acting upon the denial implied in the second. *Abit in mores incuria.*

† This theorem still awaits proof; it is stated, I believe, in Euler's correspondence with Goldbach: I re-discovered it in ignorance of Euler's having mentioned it, in connection with a theory of my own concerning cubic forms. The evidence in its favour is *induction* of the undemonstrative or purely accumulative kind, and it may or may not turn out eventually to be true. As a most learned scholar who heard this address given at Exeter remarked to me not many days ago, it is certainly by no process of deduction that we make out that five times six is thirty. I mention this, because I know some, who agree, or did agree, with Professor Huxley's published opinions about mathematics, are under the impression that the higher processes of mind in mathematics only concern "the aristocracy of mathematicians:" on the contrary, they lie at the very foundations of the subject. There are besides, and in abundance, mathematical processes which only by a forced interpretation can be brought under the head of demonstration, whether deductive or inductive, and really belong to a sort of artistic and constructive faculty, such for example as evaluating definite integrals, or making out the best way one can the number of distinct branches, and the general character of each branch of a curve from its algebraical equation.

‡ I have elsewhere (in my Trilogy published in the "Philosophical Transactions") referred to the close connection between these two cultures, not merely as having Arithmetic for their common parent, but as similar in their habits and affections. I have called "Music the Algebra of sense, Algebra the Music of the reason; Music the dream, Algebra the waking life—the soul of each the same!"

* M. Camille Jordan's application of Dr. Salmon's Eikosi-heptagram to Abelian functions is one of the most recent instances of this reverse action of geometry on analysis. Mr. Crofton's admirable apparatus of a reticulation with infinitely fine meshes rotated successively through indefinitely small angles, which he applies to obtaining whole families of definite integrals, is another equally striking example of the same phenomenon.

† *Complete* in the sense of *universal*, more *than perfect or complete* in the ordinary sense. Two criteria are absolutely fixed; but in addition to these two an additional criterion or set of criteria must be introduced to make the system of conditions sufficient. The number of such set may be either one or whatever number we please, and into such one or into each of the set (if more than one) an indefinite number of arbitrary parameters (limited) may be introduced. Now the geometrical construction I arrive at contains implicitly the totality of all these infinitely varied forms of criteria, or sets of criteria, and without it, the existence and possibility of such variety in the shape of the solution could never have been anticipated or understood. My truly eminent friend M. Charles Hermite (Membre de l'Institut), with all the efforts of his extraordinary analytical power, and with the knowledge of my results to guide him, has only been able by the non-geometrical method to arrive at one form of solution consisting of a third criterion absolutely definite and destitute of a single variable parameter. As is well known, I have made a very important use of a criterion of the same form as M. Hermite's, but containing one arbitrary parameter (limited). The subject will be found resumed from the point where I left it, and pursued in considerable detail by Prof. Cayley, in one of his more recent memoirs on Quartics in the Philosophical Transactions. M. Hermite it was who first surprised Invariantists (l'Eglise Invariantive, as we are sometimes styled) by an *à priori* demonstration that the nature of the roots or factors of quartics could in general be found by means of invariantive criteria. This was known to be possible up to the *fourth* order of binary quartics, and impossible for the *fourth*. M. Hermite showed that this negation which seemed to stop the way to further progress was an exceptional case; that whereas for the second, third, fifth, sixth, and all higher degrees the thing could be done, for the fourth alone it was impossible: as regards linear quartics, the question does not arise. I look upon this failure of a law for one term in the middle of an infinite progression as an unparalleled *miracle of arithmetic*, far more real and deeper seated than the one alluded to by Mr. Babbage in connection with the discontinuous action of a supposed machine in his ninth Bridgwater Treatise.

‡ So I found, as a pure matter of observation, that allineation (*alignement*) in ornamental gardening—*i.e.* the method of putting trees in positions to form a very great number or the greatest number possible of straight rows, of which a few special cases only had been previously considered as detached porismatic problems, forms part of a great connected theory of the pluperfect points on a cubic curve, those points, of which the nine points of inflection and Plücker's twenty-seven points serve as the lowest instances.

than I originally intended on the subject, which, as standing first on the muster roll of the Association, and as having been so recently and repeatedly arraigned before the bar of public opinion, is entitled to be heard in its defence (if anywhere) in this place,—having endeavoured to show what it is not, what it is, and what it is probably destined to become, I feel that I must enough and more than enough have trespassed on your forbearance. J. J. SYLVESTER

The remarks on the use of experimental methods in mathematical investigation led to Dr. Jacobi, the eminent physicist of St. Petersburg, who was present at the delivery of the foregoing address, favouring me with the annexed anecdote relative to his illustrious brother, C. G. J. Jacobi *—

"En causant un jour avec mon frère défunt sur la nécessité de contrôler par des expériences réitérées toute observation, même si elle confirme l'hypothèse, il me raconta avoir découvert un jour une loi très-remarquable de la théorie des nombres, dont il ne douta guère qu'elle fût générale. Cependant par un excès de précaution ou plutôt pour faire le superflu, il voulut substituer un chiffre quelconque réel aux termes généraux, chiffre qu'il choisit au hasard, ou, peut-être, par une espèce de divination, car en effet ce chiffre mit sa formule en défaut ; tout autre chiffre qu'il essaya en confirma la généralité. Plus tard il réussit à prouver que le chiffre choisi par lui par hasard, appartenait à un système de chiffres qui faisait la seule exception à la règle.

"Ce fait curieux m'est resté dans la mémoire, mais comme il s'est passé il y a plus d'une trentaine d'années, je ne rappelle plus les détails. "M. H. JACOBI

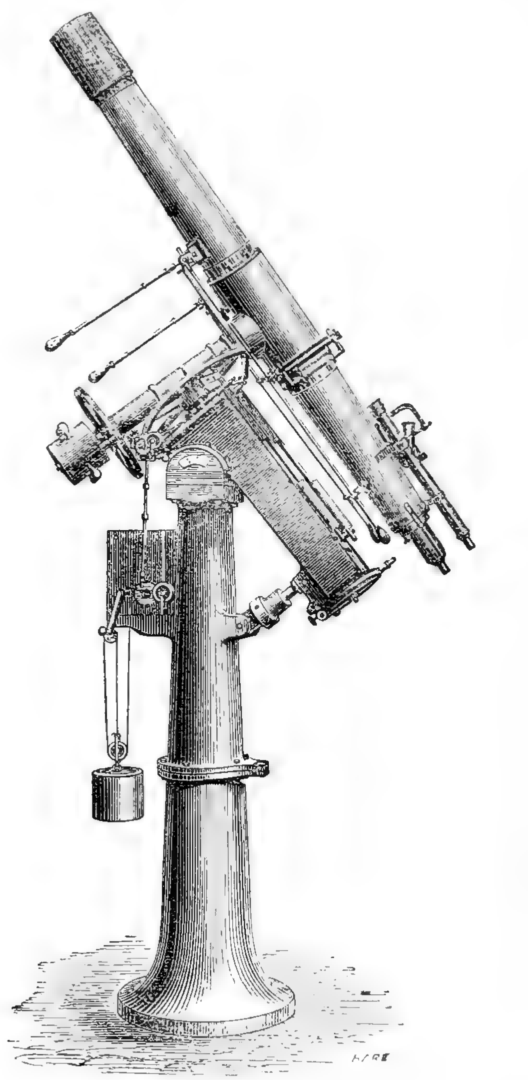
"Exeter, 24 Août, 1869."

THE NEW TELESCOPE AT ETON

IN furtherance of natural science work at Eton, an excellent telescope has been recently given to the school by the energy and liberality of some of the masters.

The instrument is a refractor, with object glass of 5·9 inches clear aperture, and 88 inches focus, and was made by Messrs. Cooke and Sons, of York, who also supplied the observatory and superintended the erection of the telescope. It is, as will be seen from the engraving, mounted equatorially on the German system, with declination circle reading to 10″ of arc, and hour circle reading to 2″ of time. The mechanical details do not, with one exception, deviate materially from the pattern usually adopted by Messrs. Cooke, whose name is a guarantee for skill of design and excellence of workmanship. The exception alluded to is in the construction of the driving clock, the speed of which is not regulated, as usual, by a centrifugal governor, or fly, alone, but by a fly supplemented by an ordinary clock escapement. This arrangement is quite new, and is the invention of the late Mr. T. Cooke, the senior partner in the firm. It was described by him in a paper read before the Royal Astronomical Society a short time ago. The details would hardly be intelligible without drawings, but the general mode of action is as follows :—

The barrel is connected with two trains of wheel-work : one (the lowest wheel of which gives motion in the ordinary way to the telescope) is terminated by a fly of insufficient power *per se* to reduce the speed within proper limits ; the other train is terminated by a half-dead escapement of the usual kind. One of the wheels of the fly-train has a broad rim, on which presses a brake actuated by a wheel in the escapement train. When the escapement is stopped, this brake presses on the wheel with sufficient force to stop the motion of the clock entirely. When the escapement is set to work the brake is released, and the fly-train moves, communicating motion to the telescope. If the speed becomes too great, so as to outrun the escapement, the latter immediately applies increased brake-power, and checks the motion of



THE ETON EQUATORIAL

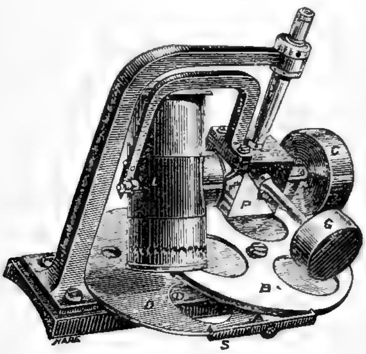
the fly ; and *vice versâ*, if from increased friction or other cause the motion is too slow, so that the fly lags behind the escapement, the brake-spring is relaxed by the latter until the due speed is regained. Thus the two trains are balanced against each other, and since one of the wheels of the escapement-train is, as in some forms of train *remontoires*, supported in a swinging-frame (which frame, in fact, controls the brake-spring), the intermittent motion of the escapement does not reach the telescope. This clock seems to work very smoothly; and not the least advantage of the arrangement is the facility with which

* It is said of Jacobi, that he attracted the particular attention and friendship of Böckh, the director of the philological seminary at Berlin, by the zeal and talent he displayed for philology, and only at the end of two years' study at the University, and after a severe mental struggle, was able to make his final choice in favour of mathematics. The relation between these two sciences is not perhaps so remote as may at first sight appear; and indeed it has often struck me that metamorphosis runs like a golden thread through the most diverse branches of modern intellectual culture, and forms a natural link of connection between subjects in their aims so remote as grammar, philology, ethnology, rational mythology, chemistry, botany, comparative anatomy, physiology, physics, algebra, versification, music, all of which, under the modern point of view, may be regarded as having morphology for their common centre. Even singing, I have been told, the advanced German theorists regard as being strictly a development of recitative, and infer therefrom that no essentially new melodic themes can be invented until a social cataclysm, or the civilisation of some at present barbaric races, shall have created fresh necessities of expression, and called into activity new forms of impassioned declamation.

the speed may be altered from sidereal to lunar rate by merely raising the bob of the pendulum through a small space, so as to diminish the time of oscillation.

For special purposes, still greater accuracy might be obtained if the escapement were worked by the observatory clock by means of a small electro-magnet connected with the pendulum of the latter. Conversely, the escapement train might, with slight modifications and the addition of a dial, be made to serve as a journeyman-clock, and show sidereal time with sufficient accuracy to be very useful in finding stars during two or three hours' work.

There is, by the way, another important modification well worthy of notice. When astronomers wish to determine the position of a star, the diameter of a planet, &c., with rigorous accuracy, they employ a micrometer with spider webs, which in the daytime are visible in the field of view. At night, however, they, or the field itself, require to be lit up. This is managed by a lamp outside and a reflector inside the tube, and to make this lamp perform effectively in every position of the telescope is a difficult matter; so difficult, in fact, on the old arrangement, that Messrs. Cooke and Sons, with their wonderful ingenuity, have entirely superseded it in this their latest instrument. Their exquisite contrivance will be seen from the annexed woodcut.



THE COOKE ILLUMINATING APPARATUS.

L is the lamp. P, a prism to reflect the light on to the tube. D, a disc with diaphrams to regulate the quantity of light. B, a disc with glasses to regulate the colour of the light. S, spring catches to clamp these discs. C, counterpoise of lamp. G, Gravity poise.

The telescope is furnished with a sufficient battery of eye-pieces, of powers ranging from 30 to 400, and also with a bifilar micrometer. The position circle is permanently attached to the lower end of the main tube.

The observatory is erected on the roof of the western tower of the New Schools. It is square, and surmounted by a revolving dome. It is obvious that an instrument erected on a tower cannot be wholly free from vibration; but the latter is reduced to a minimum by supporting the telescope on two massive trussed iron girders stretching across the tower. The floor of the observatory is supported quite independently.

Owing to the unfavourable weather of late, the final adjustments of the telescope have not been completed; but it is hoped that before long it will be in a condition for good and accurate work, such as will justify the enlightened liberality which has placed it where it is.

H. G. MADAN

REMARKS ON TERRESTRIAL MAGNETISM

(*Being the substance of a paper read at the Royal Astronomical Society, on Friday, Dec.* 10)

SOME years since I was led to the belief that earth currents and auroræ are secondary currents produced by rapid, though small, changes in the earth's magnetism.

In this hypothesis the earth was viewed as similar to the soft iron core of a Ruhmkorff's machine, and the upper and rarer strata of the atmosphere and the moist upper surface of the earth as conductors in which secondary currents would be generated whenever any change took place in the magnetism of the core.

This hypothesis is, I think, confirmed by the very interesting and valuable photographic traces of earth currents obtained by Mr. Airy, at Greenwich, in which, during times of great magnetic disturbance, the earth currents are seen to be very strong, and to vary alternately from positive to negative, lying about equally on both sides of the zero.

It has occurred to me that this method of viewing things is capable of extension, and that it ought to be borne in mind that secondary currents are produced, not only in a *stationary conductor* such as that of the Ruhmkorff's machine, where the magnetic core is made to vary, but also in a conductor which moves in the presence of a magnetic core of constant strength.

Have we not in the earth such conductors in constant motion? We have the return trades constantly proceeding at a high elevation from the equator to the poles, the upper strata of which, from their tenuity, may no doubt be considered to be conductors; in their journey they cross the lines of the earth's magnetic force: ought they not, therefore, to be the vehicles of electrical currents? My friend Mr. Lockyer has lately impressed upon me that the zodiacal light may possibly be a terrestrial phenomenon, and, therefore, that it may be connected in some way with the phenomena of terrestrial magnetism. May it not be the return trades rendered luminous through electric currents in the higher regions of the atmosphere, and may there not also be two species of auroræ, the one occurring in stationary conductors, when the earth's magnetism changes, and the other, in moving conductors, when the earth's magnetism is constant?

But again, it must be allowed that these conductors conveying currents must react on the magnetism of the earth, and we might therefore expect that at those periods of the year at which the system of currents, viewed as meteorological phenomena, change most abruptly, the earth's magnetism would also be particularly liable to change. May not this be an explanation of the excess of magnetic storms about the times of the equinox?

But besides these great terrestrial currents, we have the daily convection currents caused by the sun, which, when they reach the upper regions of the earth's atmosphere, we may imagine to be conductors; and as they also pass across lines of magnetic force, we may suppose them to convey currents. May not these, to some extent at least, account for the diurnal variations of terrestrial magnetism? If this be the case we should have a ready explanation of the likeness observed by Mr. Baxendell between the wind curves and those of the declination.

I have hitherto alluded only to atmospheric currents, but there are also oceanic currents, and more especially there is the tidal wave, which occurs twice every lunar day. No doubt the influence of the tidal wave, as a moving conductor, must be very small; but may it not help to account for the lunar-diurnal variation, which is very small likewise?

But if there is an electric current of this kind in the ocean, it ought to be detected by the system of earth current wires which Mr. Airy has at Greenwich, inasmuch as the surface of the earth and the ocean are in electric communication with each other. Mr. Airy has, if I am not mistaken, detected indications of lunar-diurnal inequalities in the results of his observations. On the other hand, he has detected no current with a single daily period that would account for the diurnal variation—a result in accordance with these views, since the currents producing such would be in the upper regions of the atmosphere.

These views are given in order to invite criticism and comment; and they will have served their purpose if they direct attention to the part played in the phenomena of terrestrial magnetism by moving conductors. It will be noticed that they leave untouched the mysterious and important connection between sun spots and magnetic disturbances. B. STEWART

P.S.—Since writing the above, Prof. Sir W. Thomson has informed me that Faraday tried to detect induction currents by tides in the Thames, but found no positive result. In an article in the *Philosophical Magazine*, Dec. 1851, Prof. Sir W. Thomson quotes this idea of Faraday, and makes a proposal to test it from tides in the Channel. He also discusses the part which may be played in the phenomena of terrestrial magnetism by moving conductors.

BRITISH RAINFALL

MR. G. J. SYMONS (62, Camden Square, N.W., December 22, 1869) sends us the following list of localities whence observations are "urgently required;" we think he will have many volunteers:—Cornwall: Falmouth, Jacobstow. Devon: Hatherleigh, Hartland, Exmoor. Dorset: Bere Regis. Oxford: Thame. Surrey: Redhill. Suffolk: Halesworth, Mildenhall. Lincoln: Kirton. Nottingham: Mansfield. Warwick: Stratford-upon-Avon. Shropshire: Bishop's Castle. Yorkshire: Milford Junction, Pateley Bridge, Kettlewell, Askrigg, Driffield, Bridlington, on the North York Moors. Lancashire: Broughton. Northumberland: Haltwhistle. Cumberland: Kirkoswald. Westmoreland: Ravenstonedale. Isle of Man: any part of the Island. Pembroke: Tenby, Fishguard. Cardigan: Aberaeron, Brecknock, Llanwrtyd. Radnor: Builth, Knighton. Montgomery: Montgomery, Llanfyllin. Merioneth: Barmouth, Harlech. Carnarvon: Pentrevoclas. Wigtown: Northern part of. Kirkcudbright: Western part of. Peebles: Peebles, Biggar. Ayr: Muirkirk. Argyle: Mull of Cantire, Ballimore, Glencoe, near Ben Cruachan. Perth: North-west part of. Forfar: Western part of. Inverness: along the Caledonian Canal, and in Lochaber. Aberdeen: North-west part of. Nairn: any part of. Banff: Southern part of. Ross: any place inland, or in Lewis or Harris. Sutherland: any place inland. Caithness: any place inland. Ireland: except from the vicinity of Belfast, Dublin, Londonderry, and Waterford, where there are many observers, returns are required from nearly all parts of the country.

THE LATE PROFESSOR MICHAEL SARS, OF CHRISTIANIA

THIS eminent zoologist died on the 22nd of October last; and his loss will be much felt by all naturalists who have benefited, as I have done, by his long, laborious, and conscientious investigation of the invertebrate fauna of the Norwegian seas.

He was born on the 30th of August, 1805, at Bergen, where his father was a shipowner. After finishing his academical studies at Christiania, and evincing at an early age his predilection for natural science, he entered into priest's orders, and in 1830 became pastor at Kinn, in the diocese of Bergen. Ten years afterwards he had charge of the parish of Manger in the same diocese. As both these parishes were on the sea-coast, Sars had constant opportunities of pursuing his zoological researches. In 1829 he published his first essay, entitled "Bidrag til Söedyrenes Natur-historie," and in 1846 the first part of his celebrated work "Fauna littoralis Norvegiæ." In 1854 he was appointed Professor Extraordinarius of Zoology at the University of Christiania, a position which he filled up to the time of his lamented death with great honour to his country, and to the satisfaction of the whole world of science. His celebrity as a zoologist, as well as a palæontologist, was fully recognised by all naturalists and geologists, and he was elected a member of several foreign scientific societies. Our own distinguished countryman, the late Edward Forbes, individually showed his appreciation of Sars's labours in eloquent pages (66 and 67) of his own posthumous work, "The Natural History of the European Seas," when he said, "More complete or more valuable zoological researches than those of Sars have rarely been contributed to the science of Natural History, and the success with which he has prosecuted investigations claiming not only a high systematic value, but also a deep physiological import, is a wonderful evidence of the abundance of intellectual resources which genius can develop, however secluded and wherever its lot be cast;" and he added that the name of this Norwegian priest, "who reaped reputation when seeking no more than knowledge familiar to every naturalist in Europe and America, in Asia, and at the Antipodes—for there are great naturalists settled far in the south, and many in the far east—is a sufficient proof that able work brings the rewards of applause and veneration, even when they be unasked for." By the observations of Sars on the development of the Medusæ he greatly advanced our knowledge of that remarkable physiological phenomenon known as the alternation of generations, which Chamisso had first indicated in the Salpæ. His last publication, "Mémoire pour servir à la connaissance des Crinoïdes vivants," caused especial interest, by showing that a race of animals, supposed to be extinct for a period so long as only to be measured by the duration of several past geological epochs, occurred in a living state in the abysses of the Norwegian seas. This discovery mainly induced the recent exploration of our own seas at great depths, which has produced such wonderful results; and the living Crinoid, or "stone-lily" (*Rhizocrinus Lofotensis*), has now been ascertained to inhabit many parts of the Atlantic from the Loffoden Isles to the Gulf of Mexico. The published works of Sars are seventy-four, and they are not less sound and valuable than numerous. One of his sons, Dr. George Ossian Sars, inherits the zoological inclinations and talent of the late Professor, and is second to none in the knowledge of the Sessile-eyed Crustacea.

It is exceedingly to be regretted that, in spite of the most rigid economy, the large family of Professor Sars is left in very impoverished circumstances, six of his children being wholly unprovided for. May I hope that naturalists and lovers of science will assist me in making a subscription for the temporary relief of this distressed family, and that they will by such tribute to his memory express their admiration of his career and services? I shall be very glad to receive any contributions.

J. GWYN JEFFREYS

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Cuckows' Eggs

I AM very grateful to Mr. Sterland for asking for further information "on some points of difficulty" in my recent paper on Cuckows' Eggs, because it shows me where I have failed in making myself plainly understood. In endeavouring to reply so far as lies in me to his questions, I will take them in order.

1. "Are they [Cuckows' Eggs] so variable as some assert?"

Mr. Sterland supports the doubt here indicated by the statement of "one of the most eminent and experienced of living oologists;" but who this oologist may be he leaves to be guessed, and I venture with all respect to remark, that quoting an anonymous authority in natural history is quoting no authority at all. I am therefore not willing to bring such experience as I myself have had into conflict with that of this eminent but nameless person. Still, as Mr. Sterland is not satisfied with the opinion on this point of the German authors* cited by Dr. Baldamus, I will here adduce the following passages :—

"Quant au genre Coucou (*Cuculus*) et notamment à l'espèce type du genre, notre Coucou Chanteur (*C. canorus*), on sait quelle étonnante diversité offre la coloration de son œuf, toujours de forme ovée, diversité telle que nous nous abstiendrons d'en aborder la description détaillée."—DES MURS, *Traité Général d'Oologie Ornithologique*, &c. Paris : 1860, p. 219.

"Ces œufs sont très-petits relativement à la taille de l'oiseau, et varient beaucoup pour la couleur. Ils sont ou cendrés, ou roussâtres, ou verdâtres, ou bleuâtres avec des taches petites et grandes, rares ou nombreuses, d'un cendré foncé, vineuses, olivâtres ou brunes, avec quelques points et parfois des traits déliés noirâtres. Nous en possédons deux du blanc le plus pur, et un autre d'une seule teinte bleu-verdâtre, pris dans un nid de Stapazin."—DEGLAND et GERBE, *Ornithologie Européenne*, &c. Paris : 1867, vol. i. p. 163.

I produce this testimony as to *facts* with the greater confidence, because the *opinions* of the witnesses differ from my own, and not one of them, so far as I can gather from their works, was acquainted with Dr. Baldamus's essay.

2 and 3. "Were these [sixteen varieties of eggs] seen to be deposited by the bird, or how were they identified as those of the cuckow? . . . . Is there not room for error here?"

The evidence on which the eggs in question were referred to the Cuckow has been printed in full by Dr. Baldamus and the translator of his essay. To repeat it here would occupy much space and, I think, be unnecessary. It is of much the same kind as the evidence with regard to most Cuckows' eggs. I will freely grant that it might be more satisfactory—if it were so my former paper would never have been written, since naturalists must then have at once accepted the theory. But, on the other hand, I have a right to ask this : If the eggs in question were not Cuckows', what birds laid them? Surely not those in whose nests they were found, because it is a fact which most oologists will confirm, that when birds lay larger eggs than usual the colouring is commonly less deep, and though exceptions may occasionally be found, yet here we have sixteen which are at the same time larger than usual, and of a colour at least as deep, supposing them to belong to the nest-owners. *Sixteen* cases are too many to be exceptional, but this is the number only of the specimens *figured* by Dr. Baldamus ; upwards of *sixty* are more or less fully *described* by him.

4. "How then is this process effected?"

In answer to this, Mr. Sterland quotes a very brief summary of my own explanation, to which I have nothing now to add.

5 to 9. The next five questions, for brevity's sake, I will not repeat. They are very pertinent, but are far more easily asked than answered, for they open a wide field of speculation and investigation, since all the hitherto unexplained phenomena of "Dimorphism," "Trimorphism," and "Polymorphism," seem to enter here. But with respect to one of the questions (No. 6), I submit that even if there were no other instance satisfying the conditions imposed by Mr. Sterland than that which I alleged, it is no true argument against the truth of what I advanced. But I think there is an indication of it in other species bearing very directly on the point. Take the Blackcap Warbler and the Tree-Pipit. The eggs of the first are well known to present at least two very different appearances, and those of the second are still more variable. Since Mr. Sterland will not allow that my Eagles fulfil his conditions (and of course he has a perfect right to do so), perhaps he will permit me to bring forward these birds. I have some reason for believing that the same hen Blackcap constantly lays eggs of similar colour. Do the birds of this species hatched from eggs with reddish shells lay eggs of the same character, or brownish ones, and *vice versâ?* If of the same character, we have such an example as is required. If of the other colour, it becomes a case in some measure of "Alternate Generation," but still reducible to a law. That there should be no law at all seems to me at least unlikely, though I fear its discovery is hard.

Certain facts of Dimorphism and Polymorphism are known, but I have not met with any attempted explanation of the phenomena even in such decided and remarkable cases as those of the Malayan Butterflies given by Mr. Wallace (Trans. Linn. Soc. vol. xxv. pp. 5-11). Why the different forms of one species of *Papilio* inhabiting the same district remain distinct is perhaps more unaccountable than that the different forms of Cuckows' eggs should be preserved, for it does not seem to me unlikely that the colour of the egg and the maternal instincts should depend upon the *hen* bird ; in which case, granting the hereditariness (if I may make such a word) of the qualities already specified, I think there would be no difficulty.

10. A full reply to Mr. Sterland's last question would lead me to anticipate much that I intend to say when you again permit me to trespass on your readers' forbearance. Consequently, I must defer it until I come to the consideration of "Cuckows' Dupes." ALFRED NEWTON

Cambridge, Dec. 11, 1869

By way of postscript of my letter of the 11th of December (for the delay in publication of which I am in no way accountable*), permit me to offer a few remarks on the communications of Mr. Dresser and Mr. Cecil Smith which have since appeared.

Mr. Dresser says (p. 218) that he "cannot quite agree with Professor Newton that Cuckows' eggs *as a rule* are subject to great variety." I am not aware that I had made such an assertion. The nearest approach to it that I can find is my statement (p. 74), that "it has long been notorious to oologists that eggs of the Cuckow (*i.e.* of the Common Cuckow of Europe —the only species I had mentioned) are subject to very great variety," and in proof thereof I have since furnished some other (and, I think, satisfactory) evidence. Mr. Dresser himself has also brought two or three additional examples which confirm my statement. For the knowledge of these I am much obliged to him, as well as for stating the result of his own experience in support of my supposition that the eggs of the same hen Cuckow resemble each other.

Mr. Cecil Smith (p. 242) seems to me to be as unfortunate in his interpretation of my remarks as he was in that of Dr. Baldamus's (p. 75, note). I feel sure that I have not "pruned and paved" down the doctor's theory so "that there is but little of the original left." To the facts alleged by that naturalist I have taken no exception—on the contrary, I have borne witness (pp. 74, 75) to their general truth ; and in the attempt to offer a reasonable explanation of them, I am certain that my "manipulation" is not open to any such charge as that made by Mr. Smith. My "cautious and limited statement" is not different from that of the doctor, nor does "it entirely sweep away" a single assertion of his as to matters of fact. Mr. Smith, apparently, thinks because I have referred to the number of Cuckows' eggs yearly found in nests of the Hedge-Sparrow in this country, without ever bearing any resemblance to the eggs of that bird—a fact, of course, fully admitted by him—that I must thereby deny the single exceptional case adduced from Germany by Dr. Baldamus ; but I have never maintained, because no likeness is to be traced in a great many instances, that none was ever perceptible, and accordingly there is no "issue of fact" between the doctor and myself. I must take the liberty of adding, that Mr. Smith, having, as I before showed, misunderstood Dr. Baldamus, has now misunderstood me ; and this being the case, it is perhaps needless for me to take up more of your space. ALFRED NEWTON

January 3, 1870

The Veined Structure of Glaciers

I THINK there is no one point in connection with glaciers more interesting than their veined structure, or one upon which so much has been written that remains equally unsettled. The difference of opinion about it between the authors who have published most upon the subject are not less remarkable than the phenomenon itself : no two are agreed, except in considering it as a constitutional feature.

Professor Agassiz maintains (*Atlantic Monthly*, Dec. 1863) that the horizontal layers of pure ice which are formed between the beds of snow from which a glacier is born, constitute many of the identical veins or plates of pure ice which pervade the glacier when it is in full life and activity ; and attributes the inclination which they make, in the latter case, to their former horizontal position, to the contortion, bending, or folding, to

* They are Naumann, Thienemann, Brehm, Gloger, and Von Homeyer. Unfortunately, Dr. Baldamus does not refer to the passages in their writings wherein this opinion is expressed ; and as most of these writings are somewhat voluminous, I have not always been able to find what are the passages meant. I presume that Mr. Sterland has been more fortunate, for he would scarcely doubt the assertions without knowing what they were, and I should be much indebted to him if he will tell me where they occur—indeed, I am uncertain which of the Brehms and which of the Von Homeyers is intended.

* [The delay in the publication of Prof. Newton's letter is owing to an oversight. It was received prior to the communications of Mr. Dresser and Mr. Cecil Smith, printed in our eighth and ninth numbers.—ED.]

which they have been subjected on their downward course; but, at the same time, he distinguishes between these veins—the result of stratification, and others which he terms bands of infiltration, and which he believes to have been formed by the infiltration and freezing of water.

The late Principal J. D. Forbes maintained ("Occasional Papers on the Theory of Glaciers," 13th letter) that the veins of stratification were annihilated at a certain point, and that at precisely the same time other veins, approximately at right angles to the former ones, were formed. These effects he referred to intense pressure.

Professor Tyndall ("Glaciers of the Alps," pp. 380, 425-6), agrees with Professor Forbes "in ascribing to the structure a different origin from stratification," and, if I understand him rightly, does not believe that *any* portion of the (approximately) vertical veins have such an origin. He divides the veins into marginal, transverse, and longitudinal structure, and asserts that all are produced by pressure, which causes partial liquefaction of the ice, and that the water is refrozen when the pressure is relieved.

If any one cause produced the whole of the veins of pure ice that are found in the imperfect ice of glaciers (which all are agreed are a constitutional feature of those bodies), it is obvious that that cause would have to be equally generally distributed. It is indisputable that all the veins are not veins of stratification, because examples have been frequently observed crossing (cutting) the strata lines at a larger or smaller angle. But although such observations prove conclusively that all the veins must not be attributed to stratification, they do not prove any more. I believe, with Professor Agassiz, for reasons advanced elsewhere,* it can be demonstrated, equally conclusively, that many of the veins which are seen in the lower courses of glaciers in the Alps are veins originally produced by stratification, and dissent entirely from the "annihilation" of Principal Forbes. But as it is proved that some have a different origin, we must look to other causes for an explanation. It is probable that the theories quoted above offer a practical solution of the difficulty, although they are unfortified by direct proofs. But I have seen examples which it was difficult to explain by either one or the other.

There is one means by which the veins might be produced, which, if not overlooked, is at least not generally advanced. All glaciers have crevasses; a glacier is known by its crevasses. The sides of all crevasses become more or less weathered and coated with a glaze of pure ice. When they close up again, when the sides join by virtue of regelation, does this leave no trace? Can it be annihilated? Or, do the two coalesced films leave their mark as a vein of pure ice throughout the generally whitish mass of the glacier? I consider a large number of the veins of pure ice which constitute the "veined structure" of glaciers as nothing more than the *scars of healed crevasses.*

It is not easy to say whether this was the meaning of the following passage, taken from p. 201 of Forbes's "Occasional Papers:" "Most evidently, also, the icy structure is first induced near the sides of the glacier where the pressure and working of the interior of the ice, accompanied with intense friction, comes into play, and the multitudinous incipient fissures occasioned by the intense strain are reunited by the simple effects of time and cohesion." Judged by his preceding pages, it is not, and I am unaware that it has been, advanced in any other place. Some of your readers may perhaps be able to throw some light upon the subject.

Dec. 13, 1869 EDWARD WHYMPER

* British Association, 1866 (Nottingham).

Irish Lepidoptera

IN reply to the note appended to the report of the Dublin Natural History Society's Meeting, Dec. 1st (NATURE, No. 6, p. 176), allow me to say that I perfectly remember the specimen of *Liminitis* to which Mr. Andrews refers, and which he exhibited some years ago as *Liminitis Sibylla* from Tarbert in the county of Limerick. It was subsequently given by him to my friend Mr. A. Dunlop, of Sutton, near Dublin, and sent to me for identification.

I examined it carefully, and it is a specimen of *Liminitis Camilla*, and *of Continental origin.* How it came to be mixed with Mr. Andrews's Irish specimens remains for him to explain.

To say that the insect is neither Sibylla nor Camilla is absurd; these are the only two species of the genus which inhabit Europe; and Camilla, to which Mr. Andrews's specimen belongs, is the most unlikely of the two to occur in Ireland, as Sybilla is found in England, but not Camilla. However, the insect is in Mr. Dunlop's Collection, and I am sure that gentleman will have pleasure in allowing anyone to inspect it.

As to *Chrysophanus Virgaurea*, there is no British specimen known, nor is there any trustworthy record of the capture of the species in the British Islands.

Chrysophanus Hippothoe (variety *Dispar*) was formerly taken in profusion in the fen districts of Cambridge and Huntingdon, but not that I am aware of in any other part of England. It has been extinct for many years as a British insect, and there is no record of its capture in Ireland at any time. Mr. Andrews's statement that he "met with" Dispar in Kerry is indefinite. Did he capture it? or did he only see it, or suppose he saw it? The most experienced collector may mistake an insect on the wing; and delighted as entomologists would be to welcome back the long-lost Hippothoe, they will require very different proof of its reappearance to any which has yet been adduced.

EDWIN BIRCHALL

Airedale Cliff, Newlay, near Leeds, Dec. 20, 1869

Deep Sea Corals

IN the postscript to Mr. J. Gwyn Jeffreys's report on the "Deep-sea Dredging Expedition in H.M.S. *Porcupine*," I notice the following sentence:—"The presence of corals at great depth will also materially alter the views generally received of the depth at which reef-builders may work, and modify to a certain extent Darwin's theory of the reefs and their mode of growth." This opinion has gained much credence, but it is founded upon error, and is a mistake. Count Pourtales has been good enough to send me the commonest corals which he dredged up off Florida and the Havana from depths greater than 100 fathoms. He has forwarded also the description of the species, and a note upon the nature of the *genera* represented in the depths of the Gulf of Mexico, and which have not been as yet described. I have received the greater part of the corals dredged up during the expedition in the *Porcupine*, and have examined the specimens carefully. Being thus acquainted with the deep-sea coral fauna of both sides of the Atlantic, and having a previous knowledge of the species of the Mediterranean, I have no hesitation in asserting that there is not one species found in these deep seas which is "reef-building" in its habit or whose structures resemble those of the true reef forms. Mr. Darwin's theory is therefore as yet as strong as ever.

Dec. 23, 1869 P. MARTIN DUNCAN

A Meteor

MY attention has just been called to an error in my letter of November 6, which appeared in NATURE, p. 58, respecting the meteor of that evening. I refer to the statement that, of the meteor-cloud, the "longest axis was in the line from the north-west point of the horizon to the pole-star." Instead of *north-west*, it should have been *south-west*, or, perhaps, more correctly, S.W. by W. WM. PENGELLY

Lamorna, Torquay, Dec. 31, 1869

NOTES

THE trigonometrical survey of England and Wales, on the scale of one inch to a mile, has been completed during the past week. It was commenced in the year 1791.

TELEGRAPHIC connection with Australia is about to be carried out by the British-Australian Telegraph Company. The work will consist of 563 miles of cable from Singapore to Batavia, and will join the Dutch line which crosses to the south-eastern extremity of Java, from which point another cable of 1,163 miles is to be laid to Port Darwin. A land line of about 800 miles will connect this with all the Australian colonies. From England to Singapore the messages will be taken by the Falmouth and Malta, the Anglo-Mediterranean, and the British-Indian Extension Companies; thus forming a complete route.

THE eighth part of Wurtz's *Dictionnaire de Chimie* has just been issued. The *Revue des Cours Scientifiques*, to which we are indebted for this announcement, calls particular attention to the articles *Eaux* and *Composés diazoïques* by M. Gautier, *Dissociation* by M. H. Debray, and *Engrais* by M. Dehérain.

THE Agricultural Academy of Poppelsdorf, near Bonn, has recently sustained a severe loss in the death of its able and energetic director. Dr. Edward Hartstein was not only a man of wide scientific attainments, but a good practical farmer, and thoroughly acquainted with the English and Scotch systems of agriculture in their more advanced phases. Appointed to the directorship of the Poppelsdorf Academy at the early age of 32, he devoted himself heart and soul to the interests of that institution, and to the advancement of agriculture in his native country. He was the author of various works on rural economy, and for some time immediately previous to his death had been busily engaged in working up the materials for a book which should combine the results of his practical experience with the most recent conclusions of the botanist, the chemist, and the physiologist. Dr. Hartstein was born in 1823, and died on the 14th ultimo, a victim to over-work. He was a member of the Royal British Agricultural Society, a distinction which he highly prized.

THE *Engineer* states that a meeting of Government science teachers was held in Manchester on Monday week, when it was resolved to submit to the Department of Science and Art an expression of regret and disapproval of the sudden and unanticipated mode in which that department has repudiated its engagements with the teachers, chiefly with reference to lectures. The received theory that public companies have no conscience seems to be very generally true of public departments, except when they happen to be dealing with interests strongly represented in the House of Commons.

M. LORTET, Professor at the School of Medicine in Lyons, has undertaken the Natural History Course at the Faculty of Sciences in that city, vice M. Jourdan, who retires.

THE Council of the Society of Arts have decided to create a new office, that of Inspector of the Educational Department, and have selected for this appointment Mr. Critchett, who has been for thirteen years Assistant-Secretary. The latter office will not be filled up.

THE series of public lectures on scientific subjects which is given every winter at the Sorbonne commenced on the 23rd ultimo, when M. Fernet discoursed on the subject of optical illusions. The other lectures comprised in this course are as follows:—Jan. 6.—M. Garnier, Mining Engineer, "The Island of Otaheite." Jan. 13.—M. A. Cazin, "The Motor Forces." Jan. 20.—"M. P. Bert, Professor at the Faculty of Sciences of Paris, "Sympathetic Nervous Actions." Jan. 27.—M. Lies-Bodard, Professor at the Faculty of Sciences at Strasbourg, "Ozone." Feb. 3.—M. Janin (of the Institute), "Sound and Light." Feb. 10.—M. Wolf (of the Imperial Observatory), "The Shape of the Earth." Feb. 17.—M. Jansen, "The Eclipse of the 18th August observed in the East Indies." Feb. 24.—M. Bouley (of the Institute), "On Insanity." March 10.—M. Faye (of the Institute), "On the Figure of Comets." March 17.—M. G. Ville, Professor at the Museum of Natural History in Paris, "Theoretical Agriculture." When shall we be able to announce a like series of lectures by men of scientific eminence, as open free to all comers in our own metropolis?

A COMMITTEE has been formed at Leipzig to collect funds for the purchase of the celebrated museum of the late Dr. Klemm, of Dresden. This museum consists of some 14,000 admirably arranged objects, illustrative of what is known in Germany as the history of civilisation. Should the committee succeed in raising sufficient money to attain their purpose, the collection will be handed over to the University of Leipzig, on condition that it is made available for all classes of society. In consideration of the scientific importance of keeping together such a collection as this, the representatives of Dr. Klemm are willing to sell it to the committee for the moderate sum of 10,000 thalers.

THE first number of the *Annales des Sciences Géologiques*, a periodical on the same plan and of the same size as the *Annales des Sciences Naturelles*, has just been issued. M. Hébert, Professor of Geology at the Faculty of Sciences of Paris, is the geological editor; M. Alphonse Milne-Edwards undertakes the palæontology. One volume, consisting of four numbers, will be published annually. The greater portion of the number before us is occupied by the first part of an important treatise by M. Louis Lartet, secretary of the French Geological Society, "On the Geology of Palestine and the neighbouring countries." This treatise embodies the observations obtained during the course of the expedition of the Duc de Luynes to the Dead Sea. M. Hébert contributes a paper "On the Lignite-bearing grit of Helsingborg and Höganäs in Southern Sweden."

WE have been requested to contradict the statement contained in our last number, that the *Journal of Botany* will in future be edited by Mr. Henry Trimen, of the British Museum. Dr. Seemann will continue to edit the journal; but greater prominence than hitherto will be given to British Botany, and that department will be under the joint superintendence of Mr. Trimen and Mr. Baker, of Kew.

A SPECIAL JOURNAL for the publication and discussion of observations of shooting-stars and bolidæ is about to appear under the editorship of M. Kieselmeyer, of Dresden. It will be published at irregular intervals dependent upon the amount of material in the hands of the editor. The price will be from 2fr. 50c. to 1fr., according to the number of subscribers.

THE culture of the Cinchona, or Peruvian bark, in St. Helena is progressing satisfactorily, The plants are all in excellent health, and have a fine, green, vigorous appearance. There are now about 4000 planted out, and it is thought a sufficient number can be obtained from them to stock the whole colony.

THE Southampton Town Council have decided to adopt the "A B C" process for the utilisation of sewage, and to make such arrangements with the Native Guano Company as may be agreed upon.

AUTHENTIC cases of the successful treatment of snake bites are of some interest. Dr. Bell supplies two in his "New Tracks in North America." On the Rio Grande, in October, 1867, two horses were bitten by the same rattlesnake, while grazing. A few hours afterwards the submaxillary, parotid, and all glands situated about the head and neck were greatly enlarged; from the nostrils and gums, a clear, mucous discharge ran down; the eyes were glairy, with the pupils greatly dilated, and the coat was rough and staring. To each animal Dr. Bell gave half-a-pint of whisky, with a little water, and half an ounce of ammonia, while the wounds were fomented with a strong infusion of tobacco, and afterwards poulticed with chopped tobacco leaves. Both horses recovered. One, although reduced in flesh, and thrown out of condition, was fit for work in a week, but the other only just escaped with his life, becoming a perfect skeleton, and only commencing to mend at the end of three months. Dr. Bell adds that a little weed, common throughout the Western States (called by Engelmann, *Euphorbia lata*, and by Torney, *E. dilatata*), is said to be a specific for the bite of the rattlesnake, but at the very time the plant was wanted it could not be found, although continually met with elsewhere, along the route, so that the experiment could not be tried.

PROFESSOR GIEBEL, of Halle, reports the results of some interesting experiments which he has made with the object of ascertaining the correctness of the popular notion that sparrows are destructive animals, feeding chiefly on grapes and stone-fruit. He found on examining the intestines of seventy-three young sparrows, between the 18th of April and the 24th of June last, that forty-six of them had fed exclusively on insects (beetles, caterpillars, &c.), and seven only exclusively on stone-fruit, the rest having all more or less fed on insects. An examination of forty-six old sparrows gave similar results; three only were fruit-eaters and the rest chiefly insect-eaters.

A HAPPY idea, very ingeniously carried out, is the Pharmaceutical or Medico-Botanical Map of the World, produced by Mr. George Barber, of Liverpool. In a very clearly printed and carefully-coloured map we are shown at a glance the *habitats* of all the medicinal plants and drugs in general use, as well as the mean annual temperature of the countries whence they are obtained. The map is published by Simpkin, Marshall, and Co.

M. E. LIPPMANN has communicated to the *Annales Industrielles* an account of the operations for sinking the Artesian Well at La Chapelle. The engineers employed by the authorities of the city of Paris to execute this great work, are MM. Degosée, Laurent, and Co. When completed, this well will supply water to one of the most populous quarters of Paris. It is intended that the well shall not only strike the water-bearing stratum—at a depth of about 2,000 feet—into which the great well at Passy penetrates, but shall extend through the stratum to a total depth of 2,950 feet. In this way, other water-bearing layers will be intersected. The work was at first commenced by the ordinary method of sinking a masonry shaft 2 metres (6ft. 3¾in.) in diameter to a depth of 445 feet through the tertiary strata which lie above the chalk. Many difficulties presented themselves, chiefly due to the looseness of the earth through which the excavation penetrated, and to the insufficient pumping-power. After two years of persistent labour, it was decided to try another system. At this period the shaft had reached a depth of 113 feet; new boring machinery driven by steam power was now set up, and until the present time the work has proceeded most satisfactorily.

ASTRONOMY

Prizes for the Discovery of Comets

THE following circular has been issued by the Imperial Academy of Sciences at Vienna :—

For several years past there have been remarkably few discoveries of new comets. The cause of this fact, which seems inconsistent with that of the wider distribution of telescopes suitable for such discoveries, may be due to the special attention that has been given to the small planets. It is, however, much to be regretted that there has been such slight increase in our knowledge of the comets, in view of the recently established connection between the shooting stars and the comets. It is exceedingly desirable that we should know more than two or three hundred out of the many thousands of comets which undoubtedly belong to our system, especially as most of those which we know move in parabolic orbits. Were our knowledge of comets more complete we should surely know of more meteor streams and comets belonging one to the other. Mindful of Herr Schumacher's words "it is natural that astronomers intrusted with the administration of a well furnished observatory should have no time left for sweeping the sky so minutely and so perseveringly as is necessary for discovering these faint bodies, whilst, on the contrary, it seems certain that to the many amateur astronomers who have less extensive means of observation hardly any more useful kind of activity could be recommended," the Imperial Academy of Sciences at Vienna is induced to propose for the discovery of comets during the three years from May 31, 1869, to May 31, 1872 eight prizes annually, consisting, as the receiver may choose, of a gold medal, or of twenty Austrian ducats representing its value in money.

The award of these prizes will be subject to the following regulations :—

1. The prize will be given only for the first eight comets discovered in each of the three years named, and only for such comets as are telescopic at time of discovery, that is, invisible to the naked eye. The comet must not have been before seen by another observer, and must be one whose appearance could not be predicted with certainty.

2. The discovery must be communicated immediately and without waiting for further observations, to the Imperial Academy of Sciences, by telegraph if practicable; and otherwise by the earliest post. The Academy undertakes to transmit the news immediately to other observatories.

3. The time and place of discovery with the plan and course of the comet must be given as exactly as possible with the first notice. This first notice is to be supplemented by such later observations as may be made.

4. If the discovery should be confirmed by other observers, the prize will not be awarded unless the observations of the discoverer suffice for the determination of the orbit.

5. The prizes will be awarded in the general meeting of the Academy held at the end of May of each year. In case the first notice of a discovery arrives between the 1st of January and the end of May, the final award of the prize will be deferred till the general meeting in May in the following year.

6. Application for the prize must be made to the Academy within five months from the time of the arrival of the first notice. Later applications will not be considered.

7. The Imperial Academy will procure the decision of the permanent astronomers of the Observatory at Vienna as to the fulfilment of the conditions in Nos. 1, 3, and 4.

The New Planet (109)

IN the *Astronomische Nachrichten*, 1779-80, there is a long and important article on Piazzi's observations by M. Argelander; also the approximate place of this planet, discovered by Prof. Peters of Clinton, New York.

The following elements of the Planet are by Prof. Peters, and are considered by him to be nearly accurate. We print in a parallel column the elements for the same planet as furnished by Prof. Axel Möller, of Lund. The latter are calculated from observations taken at Clinton on Oct. 13th, Leipzig Nov. 8th, and Lund Nov. 26th, 1869 :—

Epoch 1869, Oct. 0·0 Berlin mean time.

M_0 =	337° 1′ 3·35″	350° 53′ 28·6″
π =	55° 53′ 48·0″	
Ω =	4° 51′ 45·4″	4° 57′ 30·
ι =	7° 56′ 56·55″	8° 3′ 57·8″
ϕ =	17° 25′ 14·13″	17° 27′ 51·0″
μ =	809″580	800″476·
log a =	0·4278314.	

CHEMISTRY

Transformation of Chlorinated into Iodated Compounds

AD. LIEBEN has made important experiments on this kind of transformation. Ethyl chloride, mixed in a sealed tube with three or four times its weight of strong hydriodic acid, sp. gr. 1·9, and heated for five hours to 130°, is almost wholly converted into ethyl iodide, according to the equation—

$$C_2H_5Cl + HI = C_2H_5I + HCl.$$

In like manner ethylated ethyl chloride (butyl chloride), and amyl chloride are converted by strong hydriodic acid into the corresponding iodides, without formation of secondary products. Ethyl-chlorinated ethyl oxide $\left.\begin{matrix}C_2H_3(C_2H_5)Cl\\C_2H_5\end{matrix}\right\}O$ is converted, by an excess of strong hydriodic acid, chiefly into ethyl iodide, and ethylated ethyl iodide (butyl iodide); but there are also some secondary products formed, viz. butyl chloride, alcohols, and a substance having a carbonaceous aspect, the quantity of these secondary products increasing as the hydriodic acid is less concentrated and present in smaller quantity.

To determine whether the action of hydriodic acid is a simple double decomposition or a case of the action of masses, the converse reaction was tried by heating ethyl iodide with a considerable excess of hydrochloric acid in a sealed tube to 130°. A small quantity of ethyl-chloride was thereby obtained, together with hydriodic acid and free iodine, showing that the inverse of the first-described reaction does really take place; but the quantity of ethyl chloride, which it yields, is very small, even when the action is continued for 50 hours. The result of the two supplementary experiments, namely, the decomposition of ethyl chloride by hydrogen iodide, and of ethyl iodide by hydrogen chloride, may be represented, though somewhat crudely, in the following manner—

$$\text{(Affinity of H for I)} + (\text{Affinity of } C_2H_5 \text{ for Cl})$$
$$< \text{(Affinity of H for Cl)} + (\text{Affinity of } C_2H_5 \text{ for I}).$$

The decomposition of ethyl chloride, and its homologues by the action of hydriodic acid, is analogous to the decomposition of silver iodide by the same reagent.

As an example of the action of hydriodic acid on organic chlorides of other series, *chloroform* $CHCl_3$ was introduced, together with 11 times its weight of hydriodic acid of sp. gr. 1·9, into a sealed tube, and heated for 7 hours to 125°. The principal results of this reaction were hydrochloric acid, free iodine, and methylene iodide CH_2I_2. Now, remembering the fact, demonstrated by Kekulé, that iodides, submitted to the action of hydriodic acid, undergo an inverse substitution, the reaction just described may be explained by supposing that the chloroform is in the first instance converted into iodoform, which is then converted into methylene iodide by the action of the hydriodic acid, thus—

$$CHCl_3 + 3HI = CHI_3 + 3HCl,$$
$$\text{and } CHI_3 + HI = CH_2I_2 + I_2.$$

In other cases, the action represented by the second equation goes so far as to remove all the iodine from the iodated product formed in the first instance, and convert it into the corresponding hydride. Such, indeed, is the case with compounds belonging to the aromatic series. Berthelot [Bull. Soc. Chim. (2) ix. 30] has shown that Julin's chloride of carbon, or perchlorinated benzene, C_6Cl_6, is converted into benzene, C_6H_6, when heated to 280° with a large excess of hydriodic acid; and Lieben finds that monochlorobenzene, C_6H_5Cl, heated to 235°, for 15 hours, with from three to five times its weight of hydriodic acid, likewise yields benzene.

The action of hydriodic acid on organic chlorine-compounds appears, then, to exhibit two cases:—(1.) The chloride is easily converted into the corresponding iodide by double decomposition, whereas the transformation of the iodide into the corresponding hydride is difficult, and takes place only at high temperatures. In this case, if the experiment is well conducted, an iodide is obtained without a trace of hydride. Such is the case in the action of hydriodic acid on the chlorides of the series $C_nH_{2n+1}Cl$. (2.) The chloride is attacked by hydriodic acid with difficulty, and only at a high temperature, whereas the conversion of the iodide into hydride takes place easily, and at a comparatively low temperature. In such cases, as with the chlorides of the aromatic series, the product of the reaction is a hydride without any trace of iodide. In some cases, as that of chloroform, intermediate products are obtained, only part of the iodine being removed by the inverse reaction. [Giornale di Scienze di Palermo, v. 130.]

SCIENTIFIC SERIALS

THE *Archives des Sciences Physiques et Naturelles* for December 15, contains a paper by Professor Heer, on the Miocene Flora of Spitzbergen. The writer gives a preliminary account of the fossil plants collected and sent to him by the Swedish Polar Expedition of 1868. The number of species found in the Spitzbergen Archipelago amounted to 131, of which 123 were phanerogamic, and 8 cryptogamic. Figures and a detailed description of these are promised to appear in the Memoirs of the Stockholm Academy. The next paper is an extract of Thomsen's Thermochemical Researches (taken from Poggendorff's *Annalen*), to which Marignac has appended some valuable comments. Prof. Marignac adds a paper of his own, on the influence of water on the double decompositions of salts, and on the thermal phenomena which accompany them. The author was induced to publish this preliminary memoir in consequence of the appearance of Thomsen's results. He points out some interesting cases of retardation of chemical equilibrium, and intends to investigate them further. The rest of this number—the last of the year—is occupied by the usual *Bulletin Scientifique*, Meteorological Observations, and an index to the volume (xxxvi. N. S.)

In Polli's *Annali di Chimica applicata alla Medicina* for December, we observe, among other papers, a note on the action of hydric sulphate on iodides, by Dr. Vitali. It is generally supposed that the action referred to terminates with the production of sulphurous oxide and iodine; but Vitali has noticed, in addition, the formation of hydric sulphide and sulphur—fresh instances, consequently, of the reducing energy of hydric iodide. In a paper on Ferric Albuminate, Peretti shows that albumen is capable of dissolving Ferric oxide. The filtered solution, if evaporated at a gentle heat, dries up to a rose-coloured pellicle, which can be again dissolved in water, and coagulates at 75°. Details are given as to some of the reactions of the solution. Bellini contributes an article on the therapeutic (pharmaceutical) formulæ of sulphur. There are also several papers on dietetics, hygiene, and pathology, &c., taken from other journals, and an index to the volume, of which the present is the concluding number.

THE last two numbers of the *Revue des Cours Scientifiques* (Dec. 25, 1869, and Jan. 1, 1870), contain an elaborate paper on Vaccination, by M. Brouardel; a translation of Dr. Bence Jones's Croonian Lectures; an account of Schimper's Researches in Vegetable Palæontology, by M. Ch. Grad; and a lecture given by M. Bouchardat at the Paris Academy of Medicine "On the Mortality of Foster-children."

SOCIETIES AND ACADEMIES

LONDON

Geological Society, December 22, 1869.—Prof. Huxley, LL.D., F.R.S., in the chair. Messrs. Hopkinson, J. Sanders, and Jabez Church, C.E., were elected Fellows of the Society. The following communications were read:—1. "On the Iron-ores associated with the Basalts of the North-east of Ireland." By Mr. Ralph Tate, Assoc. Linn. Soc., F.G.S., and John S. Holden, M.D., F.G.S. The authors introduced their account of the iron-ores of the Antrim basalts, by stating that since 1790 an iron band had been known in the midst of the basalt of the Giant's Causeway, but that only within the last few years have further discoveries been made, which have developed a new branch of industry in the north-east of Ireland. The iron-ore of the numerous exposures was considered to represent portions of one sheet extending uniformly throughout the basalt and over a very large area. Indeed everywhere the iron band and its associated rock-masses present identical features, from which the authors deduced the following generalised section:—The underlying basalt gradually passes upwards into a variegated lithomarge of about 30 feet thick, graduating insensibly into a red or yellow ochre or bole of about 5–6 feet in thickness, which passes into a dense red ochreous mass of about 2 feet, charged with ferruginous spheroids consisting chiefly of a protoxide and peroxide. The spheroids are of the average size of peas; they increase in number and size towards the upper part of the band, and not unfrequently constitute that portion of it. The line of junction between the iron band and the overlying, and usually more or less columnar basalt, is in all cases well defined, and in a few instances exhibits decided unconformability. The authors discussed the several theories that may be suggested to account for the origin of the present condition of the pisolitic ore, and proceeded to point out what appear to have been the several stages of metamorphic action by which the pisolitic ore had been elaborated out of basalt. From field observations and chemical analysis, they have been led to consider the bole and lithomarge as the resultants of aqueous action in combination with acidulated gases, which, dissolving out certain mineral substances, has effected the decomposition of the basalts; and to assume that the bole underlying the iron band was a wet terrestrial surface, and that the subsequent outflow of basalt effected, by its heat, pressure, and evolved gases, a reduction of the contained oxides of iron into the more concentrated form in which they occur in the pisolite, the aggregation of the ferruginous particles being a result of the same actions. The ferruginous series, with interstratified plant-beds at Ballypalidy, was next described, and demonstrated to be of sedimentary origin; the ferruginous conglomerate resulting from the degradation of the pisolitic ore, of which it is chiefly reconstructed, and of the underlying ochres. Many additions were made to the list of plant remains from these beds; and priority of discovery of plants in the Antrim basalts was accorded to Dr. Bryce, F.G.S. Mr. D. Forbes was not prepared to admit some of the theoretical conclusions of the authors, and objected to calling in metamorphism to account for all that was hard to be understood. He could not recognise the division of beds so similar in character into two classes. He wished to know, assuming that the iron-ore merely resulted from the decomposition of the basalt, what became of all the silica and alumina which constituted three-fourths of the mass. The origin of the pisolitic ores was in fact organic. In Sweden certain lakes were regularly dredged each year for the pisolitic ore still in course of formation by means of confervoid algæ. He therefore regarded the whole of these beds as in a certain sense sedimentary, and though due to organic agency, yet still deriving their original mineral matter indirectly from the basalt. The basalt contained a considerable amount both of phosphorus and sulphur; and if the ores had been derived directly from the basalt, both these substances would have been present in them. This was an argument against any direct metamorphism. The presence of venadium afforded additional reasons for regarding these ores as formed in the same manner as bog iron and similar ores. Sir Charles Lyell had observed in the basalts of Madeira red ochreous bands, which represented old land surfaces, in one of which Mr. Hartog and he had discovered a leaf-bed containing vegetation of much the same character as that of the island at the present day. Near Catania, in a recent lava-stream, he had seen the junction of the lava with the soil of the ancient gardens; and in character the soil now under the lava resembled the red beds in Madeira. Mr. W. W. Smyth was on the whole inclined to admit the power of metamorphism to produce such changes as had been here effected. He commented on the advantages of employing this Irish ore for admixture with hæmatitic ore, on account of the abundance of alumina present. Possibly there had been some difference in the chemical character of the different flows of basalt. Mr. Evans suggested that the Ballypalidy beds might be the littoral deposits of a lake in which the pisolitic ores of the other parts of Antrim were deposited farther from the shore, and subsequently buried under a basaltic flow. Mr. Etheridge inquired whether the pisolitic ore had been subjected to microscopic examination, with a view of finding traces of organic forms, such as *Gallionella.* Mr. Tate, in reply, defended his views as to metamorphic action. He thought the uniformity in thickness and character of the pisolitic ore band over so large an area showed that it could not be a lacustrine deposit. He had not as yet examined the spheroids under the microscope.

"Notes on the Structure of *Sigillaria.*" By Principal Dawson, F.R.S., F.G.S., Montreal. In this paper the author criticised the statements of Mr. Carruthers on the structure of *Sigillaria* (see Q. J. G. S. xxv. p. 248). He remarked that *Sigillaria,* as evidenced by his specimens, is not coniferous; that the coniferous trunks found in the Coal-formation of Nova Scotia do not present discigerous tissue of the same type as that of *Sigillaria;* that no conifer has a slender woody axis surrounded by an enormously thick bark; that *Calamodendron* was probably a gymnosperm, and allied to *Sigillaria*; that although *Stigmaria* may not always show medullary rays, the distinct separation of the wood into wedges is an evidence of their having existed; that the difference in minute structure between *Sigillaria* and *Stigmaria* involves no serious difficulty if the former be regarded as allied to *Cycadaceæ;* and further, that we do not know how many of the *Stigmariæ* belong to *Sigillaria* proper, or *Favularia,* or to such forms as *Clathraria* and *Leioderma,* which may have been more nearly allied to *Lepidophloios*; that the fruit figured by Goldenberg as that of *Sigillaria* is more probably that of *Lepidophloios,* or may be a male catkin with pollen; and that he has found *Trigonocarpa* scattered round the trunks of *Sigillariæ,* and on the surface of the soil in which they grew. He agreed with Mr. Carruthers in regarding Mr. Binney's *Sigillaria vascularis* as allied to *Lepidodendron.* Prof. Morris thought that *Clathraria* and *Lepidophlois* ought to be discriminated from the *Sigillariæ,* as being rather more nearly allied with cycadaceous plants, especially the former. He pointed out the manner in which certain vascular bundles communicating between the centre of the stem of *Sigillaria* and allied genera and their bark might be mistaken for medullary rays.

"Note on some new Animal Remains from the Carboniferous and Devonian of Canada." By Principal Dawson, F.R.S., F.G.S., Montreal. The author described the characters presented by the lower jaw of an Amphibian, of which a cast had occurred in the coarse sandstone of the Coal-formation between Ragged Reef and the Joggins Coal-mine. It measured 6 inches in length; and its surface was marked on the lower and posterior part with a network of ridges enclosing rounded depressions. The anterior part of the jaw had contained about 16 teeth, some of which remained in the matrix. These were stout, conical, and blunt, with large pulp-cavities, and about 32 longitudinal striæ, corresponding to the same number of folds of dentine. The author stated that this jaw resembled most closely those of *Baphetes* and *Dendrerpeton,* but more especially the former. He regarded it as distinct from *Baphetes planiceps,* and proposed for it the name of *B. minor.* If distinct, this raises the number of species of Amphibia from the Coal-measures of Nova Scotia to nine. The author also noticed some insect remains found by him in slabs containing *Sphenophyllum.* They were referred by Mr. Scudder to the Blattariæ. From the Devonian beds of Gaspé the author stated that he had obtained a small species of *Cephalaspis,* the first yet detected in America. With it were spines of *Machairacanthus* and remains of some other fishes. At Gaspé he had also obtained a new species of *Psilophyton,* several trunks of *Prototaxites,* and a species of *Cyclostigma.* The President objected to the term *Reptiles* being applied to Amphibia, from which they were totally distinct. He questioned the safety of attributing the jaw to *Baphetes,* of which no lower jaw had been previously found. Mr. Etheridge remarked that the *Cephalaspis* differed materially in its proportions from any in either the Russian or British rocks.

"Note on a Crocodilian Skull from Kimmeridge Bay, Dorset." By J. W. Hulke, F.R.S., F.G.S. The author described a large Steneosaurian skull in the British Museum, from Kimmeridge Bay, which had been previously regarded as Pliosaurian, and was recently identified with *Dakosaurus* by Mr. Davies, sen. From the agreement of their dimensions, and their occurrence near together, the author thought it probable that this skull and the lower jaw described by him last session belonged to the same individual. It differs from the *Steneosaurus rostro-minor* in the greater stoutness of its snout, in the presence of an anterior pair of nasal bones prolonged into the nostril, and in the number of its teeth. The author proposed to name it *Steneosaurus Manseli,* after its discoverer.

"Note on some Teeth associated with two fragments of a Jaw, from Kimmeridge Bay." By J. W. Hulke, F.R.S., F.G.S. The author described some small teeth associated with fragments of a long slender snout not unlike that of an Ichthyosaur, but too incomplete to be certainly identified. The teeth are peculiar in the great development of the cementum, which gives the base of the tooth the form of a small bulb. The exserted crowns are slightly curved, smooth, cylindrical, and pointed. The attachment to the dentary bone was probably by means of the soft tissues, and the teeth seem to have been seated in an open groove in the surface of the jaw-bone. Until additional material reveals the true nature of this fossil, the author proposes to place it alone, and to call it provisionally *Euthekiodon.* The following specimens were exhibited:—Fossils and Rock-specimens from Antrim; exhibited by Ralph Tate, Esq., F.G.S. Fossils from Kimmeridge Bay; exhibited by J. W. Hulke, Esq., F.R.S.

Photographic Society, Dec. 14, 1869.—J. Glaisher, F.R.S., president, in the chair. The Secretary read a paper by Dr. Van Monckhoven, "On a new artificial light suitable for the production of photographic enlargements," of which we give the following abstract:—In M. Kirchhoff's analysis of the sun, he has shown that there are incandescent upon the sun's surface large quantities of calcium, sodium, iron, magnesium, chromium, &c. Whether these metals exist in a free state on the sun's surface, or whether they are in the form of volatile compounds, the presence of a very high temperature, *i.e.* combustion, would be sufficient to yield not only an extremely dazzling light, but also one possessed of considerable chemical power. These conditions actually exist in the sun, the chemical action of whose rays is due mainly to the presence of chromium, titanium,* and magnesium. The author has found by experiment that nearly all the metals of the alkalies and alkaline earths, as likewise many of the metalloids, when burning in oxygen, give rise to a large emission of chemical rays, due to the production of an oxide at a high temperature, and that the same phenomenon is evident when the same oxides are produced by the decomposition of the metallic salts in a volatilised condition at a very high temperature. Magnesium produces oxide of magnesium heated to whiteness by the flame. If we direct the jet of an oxyhydrogen lamp upon the carbonate or the chloride of magnesium, we produce in either case oxide of magnesium (magnesia) at a high temperature, and moreover obtain in both instances flames rich in chemical rays. So long as the salt is not entirely decomposed the light is sustained in all its brilliancy, but when nothing but magnesia remains the light loses its brightness, and at the same time the greater portion of its chemical activity. If metallic oxides (such as lime, magnesia, alumina, zirconia) are employed and heated by the oxyhydrogen flame to a very high temperature, the illumination is very brilliant; but it is much less photogenic in its character than when the oxide in a nascent condition is produced at a high temperature, as in the case of chlorides, carbonates, &c. In the latter instance the coloured lines of the spectrum inherent to each metal may be observed, but not in the former, and this circumstance induces me to believe that the chemical action of the sun is due to the cause mentioned. Magnesium is well known to emit an abundance of actinic rays; chromium is possessed of far greater chemical intensity. If dry hydrogen gas is passed through chlorochromic acid and afterwards ignited in a current of oxygen, oxide

* It is only recently that this metal has been discovered in the sun.

of chromium is produced at a very high temperature, and at the same time, a flame of such extraordinary chemical power, that chloride-of-silver paper held at a distance of twenty centimetres (eight inches) blackens sensibly in thirty seconds, or about as quickly as in full daylight. The same experiment may be conducted with equal success with chloride of titanium, which gives a blue flame of extraordinary chemical power. Unfortunately, these chlorides can be manipulated only by persons well versed in scientific research, as they become decomposed under the influence of moist gases, and the lamp then emits a considerable amount of vapour, as in the case of metallic magnesium. Magnesium, chromium, and titanium, all of which exist in the sun, are the sources of light most suitable for the purpose. The author is at the present moment occupied in establishing the coincidence of the ultra-violet rays of the spectrum with those of these metals. For the purposes of photographic enlargement, the author uses the Drummond system, substituting for the cylinder of lime, one of very pure carbonate of magnesia, free from soda, baryta, and iron, either alone in a very compressed state, or containing titanate of magnesia obtained by a mixture of chloride of titanium and carbonate of magnesia. The pillars are square at their base, three centimetres in diameter, and eight in height; they burn for an hour and a half, and cost less than half a franc apiece. They emit a very brilliant and economical light. Instead of pure hydrogen gas, ordinary coal gas, or even alcohol, together with oxygen, may be used. The preparation of oxygen, on the author's plan, is very easy, and free from danger. He employs for the purpose calcined oxide of manganese; it is then finely powdered and passed through a sieve. The chlorate of potash he uses is also pulverised and sifted; 600 grms. of brown manganese and 1,200 grms. of chlorate are well mixed by hand in an earthen vessel and sifted, care being taken not to allow any organic matter to enter, and the whole is then introduced into the wrought-iron retort A (fig. 1). The cork stopper E, covered with tinfoil, is put into its place, and the junction F,

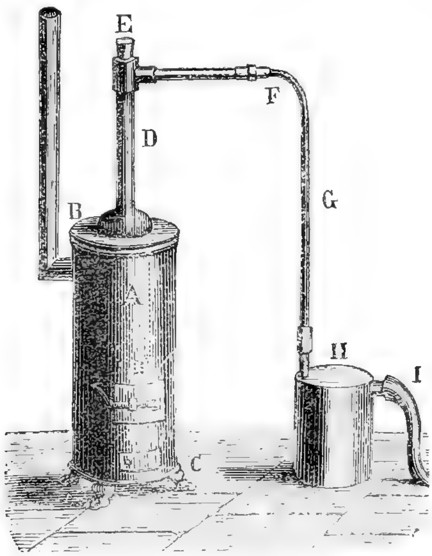


FIG. 1.

which places the retort, by means of the leaden pipe G and rubber tube I, in communication with the gas-bag, is adapted. The delivery tube (I) should be of at least half an inch internal diameter, and the wash-bottle H must be half filled with water. A small quantity of ignited charcoal is thrown into the little furnace B C, or a gas jet may be used, and after the lapse of a few minutes the india-rubber bag begins to inflate, and in twenty minutes it is full of oxygen; it is necessary during this operation to remove the weights and pressure-boards from the top of the bag. When the operation is finished and the retort somewhat cooled, the junction F is unscrewed, the cork E taken away, and warm water poured in until the retort A is filled. The water is allowed to remain for an hour, and the contents are then poured into a large jar, where, after the lapse of an hour or so, the oxide of manganese subsides. The clear water is decanted off, and the black deposit put upon a plate near the hearth to dry, after which it is again ready for repeated employment as often as desired. With ordinary native manganese a much higher temperature is necessary, the mixture having a tendency to puff up, and the operation becomes dangerous. For this reason it is advisable to use a cork stopper, E. A kilogramme of chlorate of potash yields 270 litres of oxygen, and this quantity will supply the lamp for two or three hours; thus the cost of our light, including coal-gas and the magnesia, amounts to two francs per hour. The oxyhydrogen burner used (shown in figs. 2 and 3) is very

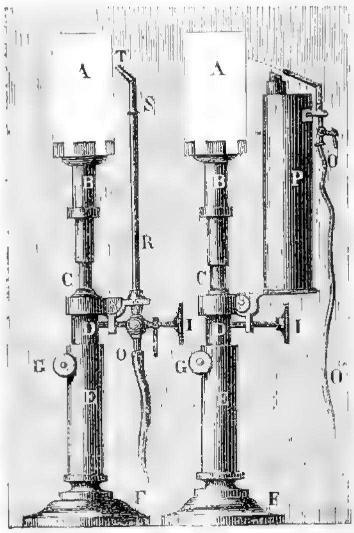

FIG. 2 FIG. 3

convenient. Those who have gas laid on in their houses will use the apparatus with two jets of gas (fig. 2); others will find it more expedient to employ the spirit-lamp arrangement (fig. 3). In both figures the same initials refer to similar details; A is the pillar of magnesia fixed upon a stem, B, which may be turned, lowered, or raised upon the rod C. E F is the stand or support, and G the pinion by means of which the light is adjusted in the centre of the apparatus. The jets for the two separate gases are formed by two concentric tubes, R, S T, sliding at S, so that the upper portion of the tube S T may be raised when it is desired to heat the top of the magnesia pillar A. Two stopcocks, O, P, lead the gases into the apparatus, the letters H and O being marked upon them to distinguish the oxygen supply-tube from that of the hydrogen or coal-gas. By means of a screw, I, the tubes R, S T, may be approached to, or removed from, the magnesia pillar. The coal-gas does not mix with the oxygen, excepting in the flame itself. The manner of employing the apparatus is exceedingly simple. The tube and stopcock marked H (connected with the supply of coal-gas), is first opened and the gas ignited; the stopcock marked O (in connection with the bag of

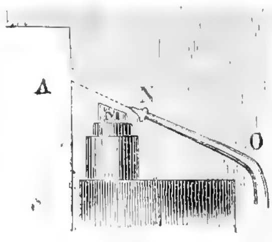

FIG. 4.

oxygen) is also opened, and the tube B then raised in such a manner that the top of the pillar A is heated by the flame, the extremity of the tube T being brought almost into contact with the magnesia. The heat soon indents the pillar, and *it is only when a cavity has been formed that the light attains its highest* *brilliancy;* at this stage the stopcock H is partially closed until the maximum amount of light has been secured. The apparatus (fig. 3) is very similar to the other. The lamp P is filled with alcohol, the wick being round and cut obliquely, as in fig. 4, the extremity of the jet N O being near enough to the wick to touch it lightly. The wick M should be almost in contact with the pillar A, which is brought about by the screw I (fig. 3). To this apparatus there is connected but one india-rubber tube, O O′, in communication with the oxygen bag. Fig. 4 shows the exact position that the jet N O should occupy in relation to the magnesia pillar. The enlarging-apparatus is shown in fig. 5. A case of

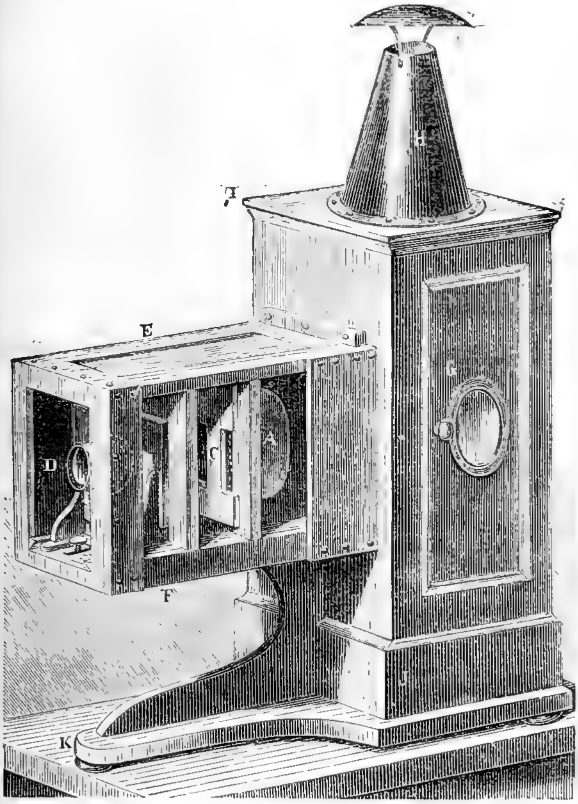

FIG. 5.

polished oak, I J, surmounted by a chimney, H, with doors at the sides, G, furnished with green glass, contains the lamp. The optical apparatus is contained in the box E; it is formed of two lenses of very white flint glass, of which one is seen at A. These two lenses condense the light and transmit it through another lens, D.* Between this latter and the lenses, A, is placed the negative to be enlarged (held in the frame C). The lenses which condense the light are prepared from very translucent flint glass rather than crown glass, which latter possesses to a considerable degree the power of absorbing chemical rays emitted at a low temperature, as is here the case. For further particulars, the reader is referred to the *Photographic Journal*, No. 212.

MANCHESTER

Literary and Philosophical Society, December 14, 1869.—J. P. Joule, LL.D., F.R.S., &c., president, in the chair. Sir Charles Lyell, Bart., LL.D., D.C.L., F.R.S., &c., and Henry Clifton Sorby, F.R.S., F.G.S., were elected honorary members of the society. Mr. R. Routledge was elected an ordinary member.—Mr. W. Boyd Dawkins, F.R.S., exhibited a stone-hammer and rude splinters of flint, brought over by Mr. Bauerman from the turquoise mines of the promontory of Sinai. These mines were worked, according to the evidence of the hieroglyphic inscriptions on the rock, by the Egyptians from the third to the thirteenth of the dynasties mentioned by Manetho. The tools and flint flakes found there in and around the workings, exactly coincide with the grooves in the rock made in the excavation, and evidently have been blunted by such use. There was no evidence that metal of any kind was used in the work. Mr. Bauerman also satisfied himself that the hieroglyphs were cut with implements similar to those used in the mining. This discovery is very important, because it opens up the question as to what tools the Egyptians used in working their wonderful monuments of granite and syenite. If it were worth their while to conduct turquoise mining with flint flakes in the Sinaitic promontory, and if they used the same tools in the hieroglyphs that fix the date of these mines—and of this there can be no reasonable doubt—it is very probable that they employed the same means for the same end elsewhere, and that, to say the least, a part of their marvellously minute sculpture in Egypt has also been wrought with flint. There is no evidence that they were acquainted with the use of steel. Iron and bronze are not hard enough for the purpose.—"On the Hades, Throws, Shifts, &c., of the Metalliferous Veins of the North of England," by Mr. J. Curry, of Boltsburn, Eastgate, County of Durham. Communicated by E. W. Binney, F.R.S., F.G.S. The new views, contained in this paper, are embraced under the consideration that the hades, throws, shifts, &c., may have been chiefly accomplished by peculiar modes of depositing of the sediments, during the contemporaneous building of the veins and strata. These modes were minutely described and illustrated by diagrams, which are requisite to convey a clear conception of the processes.

Physical and Mathematical Section, December 7, 1869.—E. W. Binney, F.R.S., F.G.S., president of the section, in the chair. "On the Mean Monthly Temperature at Old Trafford, Manchester, 1861 to 1868, and also the Mean for the Twenty Years 1849 to 1868," by G. V. Vernon, F.R.A.S., F.M.S.

PARIS

Academy of Sciences, December 27, 1869.—M. H. Sainte-Claire Deville called attention to the *Annuaire du Bureau des Longitudes* for 1870, and indicated that it contained a series of observations on the densities and co-efficients of dilatations of bodies which would render it useful in chemical laboratories.—M. C. Sainte-Claire Deville, in presenting a portion of the *Bulletin Météorologique de l'Observatoire de Montsouris*, noticed the progress of that establishment and the steps that are being taken for the cultivation of meteorology in France.—General Morin made a communication on some successful experiments which have been made on the acclimatisation of the *Cinchona officinalis* in the island of Réunion.—An extract from a letter of M. I. Pierre to M. Peligot, on the presence of potash and soda in various parts of plants, was read, in which the author stated that from his investigation of wheat, it appeared that where salt exists in the soil, both soda and potash occur in the plants grown on it, but that the latter increases in quantity up to the ear, whilst the soda is found especially in the lower parts of the plant. The amount of potash in different parts of the plant is in harmony with the amounts of nitrogen and phosphoric acid.—A note by M. S. Cloëz, on the disinfection of commercial sulphide of carbon, was presented. His process consisted in agitating the crude substance with ½ per cent. of its weight of finely-powdered corrosive sublimate, which throws down a semifluid compound of disagreeable odour. The supernatant liquid is then decanted and distilled. — Some chemical researches on copper, by Mr. T. Sterry Hunt, were communicated. The author referred to the resemblances existing between perchloride of silver and protochloride of copper, which also extend to the oxides. He described the behaviour of protoxide of copper with various chlorides, especially those of magnesium and iron, and also that of peroxide of copper with protochloride of iron.—M. Daubrée presented a note by M. Terreil on the modifications undergone by minerals by the action of saline solutions. It related to the action of the alkaline monosulphides upon the natural metallic sulphides, selenides, and tellurides, singly or in combination.—A note by M. J. Personne, on the preparation and properties of hydrate of chloral, was read. The author described the differences in the physical properties of the substances obtained by himself and M. Roussin as hydrate of chloral, and indicated that these are due to the fact that the

* In apparatus where the lenses, A, are ten inches in diameter, one of them may be removed, and the case, I J, also; then, by adjusting a reflector, it is possible to work by sunlight when the same is procurable.

compound prepared by the latter is not pure, but contaminated by the presence of a considerable amount of alcohol.—M. Dubrunfant continued the discussion on the nature of inverted sugar, by a description of his method of separating levulose from it. He effects the separation by the addition of hydrate of lime to a solution of inverted sugar, presses the crystalline magma produced, and removes the lime by treating both the solid residue and the expressed fluid with an acid. This process, according to the author, effects the nearly complete separation of the two forms of glucose, and he suggested that it might become of importance, as levulose possesses far higher sweetening powers than right glucose.—Mr. T. L. Phipson communicated a note on some substances extracted from the fruit of the walnut. From the green envelope of the fruit he obtained a yellow, crystalline substance, of little stability; this, in a few hours, produced a black, amorphous, resinous substance, $C_6 H_6 O_7$, which the author called *regianic acid*. With alkalies it forms soluble salts of a magnificent purple colour, and with oxide of lead a violet-brown insoluble salt. For the yellow body he proposed the name of *regianine*. A substance occurring in the episperm of the nut was called *nucitannine;* it is the cause of the harsh taste of that skin. From it, by treatment with mineral acids, the author obtained glucose, ellagic acid, and a red, insoluble body, which he named *rothic acid*. Its composition was said to be $C_{28} H_{12} O_{14}$. The green envelope, when fresh, absorbs oxygen with avidity from the air; when mixed with soda, it absorbs oxygen much more rapidly than phosphorus.—In a note on the simultaneous action of the intra-pilar current and nascent hydrogen upon organic acids, M. E. Royer described his treatment of oxalic acids by these agencies. Concentrated solution of that acid, placed in the porous cell of a Grove's battery, furnished a considerable quantity of formic acid in a few days, the oxalic acid having been split, and hydrogen having combined with each of the two half-molecules. No carbonic acid was set free.—M. Delafosse presented a report upon M. Kokscharow's contributions to the mineralogy of Russia, indicating the general character of that work.—M. Feil exhibited some specimens of heavy glass (Faraday's glass), prepared by a new process which enables it to be produced in large masses. He also sent in some examples of artificial gems.—A note by M. M. A. Gaudin, on the production of artificial gems, was also communicated; it was accompanied by a small collection of specimens.—A memoir was presented on the general movements of the atmosphere, by M. Peslin; also one on the graduation of galvanometers, by M. P. Blaserna; and another, containing the first part of a new method for the solution of problems in mechanics, by M. Piaron de Mondesir.—Of biological papers, M. Lacaze-Duthiers communicated a first memoir on the morphology of the mollusca, relating to the *Gasteropoda*. To this we may probably refer elsewhere.—M. P. P. Dehérain presented a paper on the metamorphoses and migrations of the proximate principles in herbaceous plants, in which the author traced the course of the more important vegetable compounds from one set of organs to another during the life of the plant, and indicated the changes which they undergo in different parts. He ascribed the transport of soluble materials from one part of a plant to another to the varying amount of aqueous evaporation from the surface. The accumulation of insoluble proximate principles in the seed was also accounted for by the author on the supposition (experimentally arrived at) that wherever in a system fully charged with liquids there is a point at which the dissolved elements become insoluble, they tend towards that point in order to maintain the equilibrium. Of the means by which the soluble elements are converted into insoluble ones, the author attempted no explanation.—M. Milne Edwards presented a note by M. Balbiani on the constitution and mode of formation of the ovum in the *Sacculinæ*, in which that author contests some of the points insisted on by M. E. van Beneden in a former paper (see NATURE, p. 246).—The question of the antiquity of the horse in Egypt formed the subject of notes by MM. F. Hément, F. Lenormant, and Faye. M. Lenormant disposes of the passage in Genesis in which *mules* are supposed to be referred to. He seems inclined to consider that the word translated mules (which occurs nowhere else in the Bible) really signifies hot springs. M. Faye, in opposition to all authority, holds fast by the ordinary modern version, and also cites the passage in the same book in which horses are mentioned among the animals taken by Joseph in exchange for corn during the years of famine in Egypt. From the fact that horses are here familiarly mentioned, M. Faye infers that their employment in Egypt as domestic animals must then have been of long standing.—M. E. Decaisne communicated a paper on suckling by mothers; and Mr. T. L. Phipson a note on the explosion and fall of meteorites. Papers were also presented by M. Bonjean, on the detection of hydrocyanic acid and cyanides in cases of poisoning; by M. Guyot, on the toxical effect of rosolic acid; by M. Trouvé, on the employment of electricity in seeking metallic bodies in wounds, &c.; by M. L. Colin, on telluric emanations and their connection with fevers; by M. Gouteyron, on the influence of the shell of iron vessels upon the compass; by M. Jouglet, on the production of an explosive powder by the action of coal-gas upon nitrate of copper; and by M. Dupuis, on a new hydraulic lever.

DIARY

THURSDAY, JANUARY 6.

ROYAL SOCIETY, at 8.30—Some Account of the Suez Canal: J. F. Bateman, F.R.S.—On the Mineral Constituents of Meteorites: N. Story Maskelyne.—On Fluoride of Silver: G. Gore, F.R.S.

EXERCISES in PRACTICAL CHEMISTRY:

Qualitative Analysis. By A. G. VERNON HARCOURT, F.R.S. Lee's Reader in Chemistry at Christ Church, Oxford, and H. G. MADAN, F.C.S. With numerous Illustrations.

"The plan of the book appears to us to be admirable, and the directions given for performing the various operations involved in the course are wonderfully precise and clear."—*Chemist and Druggist.*

Second Edition, with Solutions.

CHEMISTRY FOR STUDENTS. By

A. W. WILLIAMSON, Phil. Doc., Professor of Chemistry, University College, London. Extra fcap. 8vo. Cloth. Price 8*s.* 6*d.*

"This volume is really a too rare example of what a good elementary text-book in any science ought to be: the language, brief, simple, exact; the arrangement logical, developing in lucid order principles from facts, and keeping theory always dependent upon observation; a book that keeps the reason of the student active while he strives to master details difficult but never without interest, and that furnishes him with means for practising himself in the right management of each new tool of knowledge that is given to him for his use."—*Examiner.*

Extra fcap. 8vo. cloth, price 7*s.* 6*d.*

AN ELEMENTARY TREATISE ON

HEAT, with numerous Woodcuts and Diagrams. By BALFOUR STEWART, LL.D., F.R.S., Director of the Observatory at Kew.

"This compact little treatise is commendable both as an elementary exposition of the chief phenomena of heat and their practical applications, and also as a brief exposition of the philosophical theories which have recently given a new interest to the phenomena. The structure of the work is also excellent." —*Fortnightly Review.*

Demy 8vo. cloth, 856 pp., price 21*s.*

DESCRIPTIVE ASTRONOMY. A Hand-

book for the General Reader, and also for practical Observatory work. With 224 Illustrations and numerous Tables. By G. F. CHAMBERS, F.R.A.S., Barrister-at-law.

The aim of this work, briefly expressed, is general usefulness, whether in the hands of the student, the general reader, or the professional observer. Great pains have been taken to present the latest information on all branches of the science. The development of Astronomy is now so rapid that unless an author exercises constant vigilance his book must fall behindhand: and it is believed that this volume not only contains the most recent discoveries and deductions, but that in it will also be found information hitherto to be met with only in the publications of learned societies, difficult of access and inconvenient for reference even to the Astronomer, and absolutely out of the reach of the general reader.

Extra fcap. 8vo. price 7*s.* 6*d.*

A SYSTEM OF PHYSICAL EDUCATION.

Theoretical and Practical; with numerous Illustrations drawn by A. MACDONALD. By ALEXANDER MACLAREN, The Gymnasium, Oxford.

"It is marked in every line by good sense, and is so clearly written that no one can mistake its rules. We earnestly hope that the book will find not only many readers, but earnest disciples."—*Lancet.*

ANALYSIS." Lectures delivered in 1868. With Appendices, Engravings, Maps, and Chromo-lithographs of the Spectra of the Chemical Elements and Heavenly Bodies. Royal 8vo. 21*s.*

FORCE and NATURE: ATTRACTION

AND REPULSION. The Radical Principles of Energy graphically discussed in their Relation to Physical and Morphological Development. By C. F. WINSLOW, M.D. 8vo. 14*s.*

"Dr. Winslow's treatise is one which deserves thoughtful and conscientious study."—*Saturday Review.*

Second Edition.

Mr. WALLACE'S "MALAY ARCHI-

PELAGO:" The Land of the Orang-Utan and the Bird of Paradise. A Narrative of Travel, with Studies of Men and Nature. Two Vols. Crown 8vo. With Nine Maps and more than 50 Illustrations, 24*s.*

"A vivid picture of tropical life, which may be read with unflagging interest, and a sufficient account of his scientific conclusions to stimulate our appetite without wearying us by detail. In short, we may safely say that we have seldom read a more agreeable book of its kind."—*Saturday Review.*

SIR C. W. DILKE'S "GREATER BRI-

TAIN." A Record of Travel in English-Speaking Countries (America, Australia, India) during 1866 and 1867. With Illustrations. Fifth Thousand. Crown 8vo. 6*s.*

The Times.—"Sir Charles Dilke's account of his tour in the West is delightful reading from first to last. Even when we differ from him, we are always ready to admit the industry of his research and the accuracy of his information, as well as his exceedingly clear way of stating his views. As a mere work of travel his book is exceedingly pleasant reading, and it gives one, in a comparatively small compass, an infinity of information of the sort one most cares to have. Above all, it is eminently suggestive, and what we should pronounce its highest merit is not so much the knowledge it communicates as the craving it excites for more."

Saturday Review.—"Sir Charles Dilke has written a book which is probably as well worth reading as any book of the same aims and character that ever was written. Its merits are, that it is written in a lively and agreeable style, that it implies a great deal of physical pluck, that no page of it fails to show an acute and highly intelligent observer, that it stimulates the imagination as well as the judgment of the reader, and that it is on perhaps the most interesting subject that can attract an Englishman who cares for his country."

A HISTORY OF CHEMICAL THE-

ORY, from the Age of Lavoisier to the Present Time. By AD. WURTZ. Translated by H. WATTS, F.R.S. Crown 8vo. 6*s.*

Pall Mall Gazette.—"The discourse, as a *résumé* of chemical theory and research, evinces singular luminousness and grasp. A few judicious notes are added by the translator."

HABIT AND INTELLIGENCE, in their

Connexion with the Laws of Matter and Force. A Series of Scientific Essays. By JOSEPH J. MURPHY. 2 vols. 8vo. 16*s.*

Saturday Review.—"We are pleased to listen to a writer who has so firm a foothold upon the ground within the scope of his immediate survey, and who can enunciate with so much clearness and force propositions which come within his grasp. There is much boldness and breadth in his conception of his subject, and much fresh and genuine ability in his mode of making good his main propositions."

A TREATISE ON NATURAL

PHILOSOPHY. Volume I. By Sir W. THOMSON, LL.D., D.C.L., F.R.S., Professor of Natural Philosophy in the University of Glasgow, and P. G. TAIT, M.A., Professor of Natural Philosophy in the University of Edinburgh. 8vo. 25*s.*

"No book in the English language on that subject can be so little dispensed with. In form it is a book, but in substance it is a library."—*Scotsman.*

A HANDBOOK OF PICTORIAL ART.

By the Rev. R. ST. J. TYRWHITT, M.A. With Coloured Illustrations, Photographs, and a Chapter on Perspective by A. MACDONALD. 8vo. half-morocco, 18*s.*

"His book will be found, as he trusts it may, 'a progressive and coherent system of instruction, in which one step may lead properly into another, and the earlier processes or exercises be a consistent preparation for the later and more elaborate ones.'"—*Art-Journal.*

A NARRATIVE OF A YEAR'S JOUR-

NEY THROUGH CENTRAL AND EASTERN ARABIA, 1862-3. By WILLIAM GIFFORD PALGRAVE. Fifth and Cheaper Edition, with Map, Plans, and Portrait of Author. Crown 8vo. 6*s.*

MACMILLAN & CO., LONDON.

THURSDAY, JANUARY 13, 1870

GOVERNMENT AID TO SCIENCE

IN our present issue will be found a letter from Mr. Wallace on Science Reform, a subject which we lately brought before our readers, and which is attracting, at last, the attention which its immense importance demands.

We have the greatest respect for Mr. Wallace, and therefore willingly give him the opportunity of stating his views, though we entirely dissent from them, and though we regret to see such a question as this dealt with in what we must describe as a narrow spirit calculated to win only popular approval. Mr. Wallace's letter opens with a denunciation of the Education movement as a madness of the public mind, and with an imputation upon the Science Reform movement as a scramble for the loaves and fishes. It is only consistent with such an exordium that the benefits of Science should be depreciated, and that its cultivation should be spoken of as a matter more of personal than of national concern.

"The broad principle I go upon," says Mr. Wallace, "is this—that the State has no moral right to apply funds raised by the taxation of all its members to any purpose which is not available for the benefit of all." And further on he writes: "I maintain that all schools of art, or of science, or for technical education, should be supported by the parties who are directly interested in them or benefited by them." We understand Mr. Wallace to mean by these and many similar passages, that the main result of cultivating Science is merely the gratification of those directly engaged in the pursuit, and that they who do not take this personal interest in it derive little or no benefit from it; and hence, that it would be unjust to tax the bulk of the community to enable a few individuals to indulge their philosophical tastes. If that is not the position which Mr. Wallace desires to take up, we must declare our inability to understand the letter before us; if the position be tenable, we need hardly say that no greater error can be committed than that of seeking aid to Science from the State.

But is it tenable for a moment? Is it really necessary to tell any educated man of the nineteenth century that science, art, literature, with one or two other matters, are simply civilisation; and that civilisation affects, not particular classes, but whole communities? To confine ourselves to our own province, Science, does Mr. Wallace really believe that the discoveries of chemists, naturalists, astronomers, and physicists do not directly benefit even the ignorant masses who cannot appreciate them? Does he know of a single class, we might say a single tax-paying being in England, who does not derive direct advantages from contrivances and processes which place at his disposal properties of matter and laws of nature unknown to uncivilised people? The material results of scientific labour, such as superior clothing and dwellings, more varied food, better medical and surgical appliances, sanitary improvements, easier locomotion, are accessible to all in proportion to their means, however ignorant they may be of the scientific principles to which they are indebted for them,—as accessible to them as to the very philosophers by whom those principles were discovered and applied. Where, then, is the injustice of taxing all classes, in proportion to their means of commanding the results of science, for advantages which, if not so taxed, they would obviously gain at the cost of others? We are surprised to find it necessary to insist on truths of so elementary a character.

Justice to the taxpayer may be a good electioneering cry, but in such a discussion as the present it will command no hearing. The question for us to consider is whether the taxpayer shall possess greater material advantages than those he now enjoys, and by what agency they may be most efficiently conferred on him: whether, as a nation, we shall strive for a still higher civilisation, and how it is to be attained: whether these objects will come to us unsought, or whether, as a nation, we must exert ourselves vigorously and systematically to gain them. The resulting benefit to the taxpayer will, we need not doubt, far exceed the price he pays for it.

At present, the British taxpayer contributes to the maintenance of a Royal Observatory, of a School of Mines, of a Museum of Natural History, of a Museum of Art, of an Ordnance Survey. The advocates of the *status quo* are bound to show, not merely that catalogues of stars, collections of minerals, animals, statues, mosaics and paintings, and elaborate maps of the kingdom are useful to the taxpayer, but that no other institutions can be added to these with advantage to him, and that those we have named have attained to absolute completeness and perfection, admitting of no further development or improvement. The existence of these institutions settles, once for all, the principle that it is just to tax the community for Science. If not, abolish them. But if taxation for these particular objects be just—which even Mr. Wallace does not deny—then the question whether there are not other objects that should be added to them is one that may fairly be asked.

The examination of this question involves the passing in review of all existing, and all possible, scientific institutions, in order to select those which are properly matters of national concern; the principle of selection being that the nation should charge itself with those only which have the two-fold character of general utility and of being beyond the means of individuals to maintain; it also involves the consideration of the mode in which the scientific affairs of the nation should be administered.

A recent article in the *Pall Mall Gazette* powerfully exposes the failure of local, as contrasted with central, administration. The principles so ably contended for by our contemporary are perfectly applicable to the business of science. The time indeed is gone by for declamation against centralisation. The bugbear of the past has become the necessity of the present. Armies, fleets, railroads, telegraphs, commerce, literature, enterprise in every form, even well-ordered private households, as pointed out in the article to which we refer, are all examples of centralisation—and the tendency is daily to add to the catalogue. It might have been better that each man should suffice for himself, but as a matter of fact he does not. He relies on co-operation for the attainment of objects which he cannot compass alone, and however small the number who so unite for a common purpose, one usually directs the operations. What is true of individuals is true of a nation. Nothing that concerns the well-being of the community can be, or is, left to the chance efforts of individuals; an organisation is formed with a directing, a centralised authority, to which the whole body defer.

This is now wanted in England for Science, which cannot be cultivated without system, nor can it be governed without system. In a former number of this journal an article from the pen of Prof. Roscoe gave an interesting picture of the scientific organisation of Germany, which may be taken as typical of the Continent. Their arrangements, which carry Government intervention to a point not as yet contemplated by anyone in England, so far from having the deadening effect imputed to Government aid, has produced in large numbers men of the highest attainments and the largest and most original views, and is developing a continuity of results of the greatest practical and theoretical value. The physical education and intelligence of the people is confessedly ahead of that which the same classes in England can boast. The arts in which we once justly claimed pre-eminence are in many instances now more advanced with them than with us mainly because the principles on which they depend are, more assiduously studied, and the artisans by whom they are practised more thoroughly instructed by them than by ourselves. Many branches of trade in England already painfully attest their superiority. As a matter of fact, individual enterprise, which it is so easy glibly to pronounce the incarnation of vigour, has not borne the fruit at home which Government support, with its supposed emasculating tendency, has yielded abroad.

Are we, then, to fall back in the race of nations, to see our trade and our manufactures dwindle away, and our naval and military systems take second rank, because there is an apparent noble independence in the attempt to do single-handed what single hands are proved incapable of doing? We assert that, other things being as nearly equal as variations in religion, customs, and form of government will admit, the degree of cultivation of Science by nations will ultimately determine their places in the human family. No nation on earth has a greater abundance of natural resources and of accumulated wealth than we; no people have higher gifts or nobler aspirations; none need less fear despotic interference from its Government; no nation, therefore, is better qualified to carry out a system which has proved so successful in less-favoured countries.

The question that presses for decision is, What shall we call on the Government to contribute to scientific advancement, and in what manner shall the scientific administration of the future be constituted? The present Government is ready, we doubt not, to perform its part, if only the necessity be shown by competent testimony to exist. It is the duty of men of science, who alone can speak on the subject with authority, to give this testimony, and to help the Legislature to place on a footing worthy of a great nation a department of its duties which has hitherto been, to a most injurious extent, overlooked.

THE THAMES SUBWAY

SEVERAL attempts have been made to pass under the Thames. The chalk and alluvial deposits of the valley at Gravesend would even now offer formidable, if not insurmountable, difficulties to the attempt, once made, to tunnel through strata with water sources so unmanageable. The Thames bed at Limehouse had hidden dangers, which, however, did not succeed in stopping the bold attempt, made some forty years since, to pass beneath the river—an attempt carried in fact to a successful issue in spite of innumerable difficulties, but at an overwhelming expense. The skill and ingenuity displayed were equal to the occasion, but the object attained was not commensurate with the magnitude of the work, and for years it served rather as a warning than an example to be followed.

A better geological knowledge of the Thames valley has, however, been gradually acquired during the last half-century; and it has become evident that while some parts of the valley present the greatest difficulties to the execution of any such work as a tunnel under the river, other parts present conditions singularly favourable for such works. It is found that the chalk *e*, Fig. 2, which disappears at Croydon and reappears at Watford, passes under London at a depth of from 200 to 300 feet; that next over the chalk come beds of sand, shingle, and clay, from 80 to 100 feet thick taken together, *c* and *d*; next above these is a single massive formation of clay, in round numbers from 100 to 200 feet thick under London, and acquiring a still greater thickness—as much as 450 feet—at places not far distant. This clay is so compact and tenacious, that, except in a few places, it is perfectly impervious to water. The various railways in the neighbourhood of London, as at Primrose Hill, Copenhagen Fields, Norwood, and elsewhere, show how readily tunnels can be made through it. It has also been ascertained that this clay, known to geologists as the London Clay, though thin and uncertain at Limehouse, dips westward from that place and gradually acquires a greater thickness, until at London Bridge it forms a mass 129 feet thick. It therefore became evident that while, at and below Limehouse, any tunnel passing under the Thames would have to pass through the soft and permeable beds of sand and shingle lying between the London Clay and the chalk—beds charged with water—forming in fact originally the great water-bearing beds under the London Clay at London, and therefore almost impassable to any tunnel under the Thames; above Limehouse, and thence to London Bridge, the gradually increasing mass of London Clay presents ground more and more favourable for the execution of such a work. If a place could be found where, on the one hand, without going to too great a depth, the alluvial beds on the surface and any accidents in the Thames bed itself, and on the other hand the beds of sands and shingle below the London Clay, could be avoided, while at the same time the intermediate London Clay was thick enough to allow of the passage of a tunnel and for a sufficient thickness of roof and floor, it was clear that at such a place the conditions for the construction of a tunnel would be as favourable as could be desired.

The first to apply this knowledge was Mr. P. H. Barlow, C.E., F.R.S., who fixed upon a spot intermediate between London Bridge and Limehouse (where the thickness of London Clay must be about 80 ft.), and at a sufficient distance below London Bridge to render an underground passage of the Thames a work of great public utility. A space of vacant ground near the western entrance to the Tower was obtained from the Crown; and on the Middlesex side a small wharf offered sufficient width for the tunnel to pass under, and be carried to the shaft in Vine Street. Allowing for any likely greater depth of a former channel, or for any effect the river might have had on the clay, Mr. Barlow considered he would be safe in allowing a minimum thickness of 20ft. of London Clay to exist between the river and the top of the tunnel—a conjecture, the correctness of which has been fully proved in the execution of the tunnel; for not the slightest percolation of water from the river was detected during any part of the work. It is a question, in fact, whether a less depth might not have sufficed. Greater difficulties were apprehended in the making of the two shafts, as the gravel on either side of the river was known to be charged with water—that on the Middlesex side especially. On the north side of the river the ground rises at Tower Hill, and thence towards the City, to a height of about 40ft. above Thames high-water mark; and the London Clay is capped by a thick bed of gravel, the spring at the base of which supplies so many of the City pumps. This gravel, however, does not slope down to the river, but is cut off at the sloping ground. When the shaft on the north side came to

FIG. 1

be made, it was found, after passing this 14ft. of made ground, that the site of it was exactly on this intermediate hill of clay, and that the gravel which thinned out only a few feet higher had therefore been escaped. The shaft consequently was carried without difficulty through the 14 feet of made ground and 44 feet of London Clay to a depth of 58 feet. On the south side, the gravel, alluvial, and made soils, *a*, were found to be 35 feet thick, and charged with water, which rose and fell with the tide (highest just before low water) in the river, to the extent of 3 feet. By the use of iron-tubing, a passage through has been effected, although with more difficulty, and the shaft carried to a depth of 17 feet in the clay *b*, or a total depth of 52 feet. Between these two points Mr. Barlow laid the tunnel at a slight curve, so as to have a depth in the centre 18 feet greater than at the ends. The shafts have a diameter of 10 feet at top and 8½ feet at bottom. The tunnel is 7 feet in diameter, and is formed by cast-iron tubing in lengths of 1½ feet each, each ring being composed of thin segments with a key piece. An iron shield, devised by Mr. Barlow, was pushed on in advance of the work, and the tubes fixed in as soon as the requisite length of excavation had been completed, and the small space left between the clay and tube filled in at once by concrete. The work was carried on day and night, and advanced without interruption. No subsidence occurred in any part, and a regular and steady progress of 9 feet daily was made. Mr. Barlow, junior, is the engineer of the work, and Mr. Greathead the contractor; and the whole plan and execution of the work does very great credit both to the projector, Mr. Barlow, and to the engineer and contractor. With the exception of a slight leak in the iron tubing of the shaft on the south side, and which has been remedied after but a short delay, not the slightest mishap has occurred in the execution of the work, nor has a single fatal or even serious accident happened to any of the men. Last month the junction between the north and south side was effected, and the error of direction from the two ends was found not to amount to one inch. The passage under the river will be made in an omnibus, by means, probably, of a stationary engine; and lifts on either side will take the passengers up and down. A few minutes will suffice for the journey, and it is hoped that the work may be opened to the public in a few weeks. A remarkable feature of this interesting work has been its small cost. Mr. Barlow's estimate was 16,000*l.*, and it is now tolerably certain that the entire cost will be under 18,000*l.* Another feature has been the rapidity of execution. The shaft on the north side was commenced on the 16th of February last. On the 26th of April the tunnel, which is 1,320 feet long, was commenced, and on the 8th of October the passage under the river was safely effected. Before the public at large was aware that another Thames Tunnel was completed, the old London wonder has been duplicated.

As the object has been chiefly to speak of the geological problem, a section is annexed to show the structure of the ground at this part of the river.

FIG. 2

Very few fossils were found, and these chiefly in the clay of the north shaft. They consist of *Cryptodon angulatum*, *Corbula globosa*, *Pinna affinis*, *Dentalum nitens*, *Fusus*, and column of *Pentencrinite*. In the tunnel pieces of wood pierced by the *Teredo*, and some teeth of Shark, were met with. As the London Clay thickens to the west and north-west, and extends uninterruptedly to Windsor on the one hand and to Watford on the other, covered in places near London by beds of gravel and sand, which never, however, exceed thirty to forty feet in thickness, and rarely exceed fifteen feet, there is thus in this area a formation which lends itself singularly well to the construction of subways and tunnels.

J. PRESTWICH

THE MAMMALIA OF SWITZERLAND.

Faune des Vertébrés de la Suisse. Par Victor Fatio Dr. Phil. Vol. I. *Histoire Naturelle des Mammifères.* (H. Georg, Genève et Bale, 1869.)

M. FATIO'S book is one which will be valuable to all Swiss naturalists, and to those who take an interest in the productions of the mountainous region of central Europe. It fulfils its function admirably as far as it goes, but, like all works treating of local Faunas or Floras, its general interest is diminished in proportion to the diminution of the area investigated. It has not, for example, the importance or value to a distant reader which such a volume as the "Naturgesch. der Säugethiere Deutschlands und Mitteleuropas" of Blasius possesses; but to local naturalists it will be as useful as are the various volumes on British Zoology published by Mr. Van Voorst, to British zoologists. At the same time, there is always a gain where there is a loss in these matters: what we lose in comprehensiveness we gain in detail; and accordingly in M. Fatio's book we find much that is valuable on account of the great care which he has taken in *personal* investigation; whilst the interest of the whole subject is enhanced by the peculiar and varied conditions of the ice-ploughed Switzerland, to which it relates. Such a valley as that of the Rhone in the Valais presents conditions of climate and vegetation comparable with those of the southern shores washed by the Mediterranean; whilst an extensive region of perpetual snow is within a few hours' walk of this favoured spot. The Alpine valleys of the Grisons, again, present peculiar conditions in their great elevation. M. Fatio finds, however, that the encroachments of man, and his destruction of forest, have a more powerful influence on the distribution of animals than mere circumstances of altitude.

M. Fatio gives the number of mammals inhabiting Switzerland in the wild state—that is, excluding the cat, dog, horse, ass, ox, sheep, and goat—as fifty-eight, or as sixty-one, if the rabbit (which is not indigenous, but has been imported of late years) be reckoned, and the two minute forms, *Sorex pygmæus* and *Mus minutus*, which have been said to occur, but which M. Fatio has not himself succeeded in finding. This list does not include the ibex, the stag, or the *Mus agrarius*, which have become extinct. Some mammals which occur in adjoining countries are remarkable for their absence in Switzerland: thus, the two bats *Rhinolophus clivosus* and *R. Euryale*, which occur in Lombardy, *Mus agrarius*, occurring near the Rhine on the north, and by Como to the south, *Arvicola subterraneus*, also found near the Rhine, and *A. Savii*, found in Lombardy, are not met with in Switzerland.

M. Fatio has increased the catalogue of Swiss mammals, as given by some of his predecessors, by the addition of nine species of bats, two insectivora, and four rodents, one of which is considered a new species altogether.

This new species of M. Fatio, is a little black mouse, very much like the common house mouse (*Mus musculus*), but having a very dark black-coloured fur; the two presenting much the same contrast as do the *Mus rattus* and *Mus Alexandrinus*, which M. Fatio agrees with M. Arthur de l'Isle in considering one and the same species. The new mouse, however, which is called *Mus Poschiavinus*, from the locality where it was observed, presents more important differences when compared with *Mus musculus* than those of colour and proportion only, The palatine ridges in *M. Poschiavinus* are *four* in number, in place of *five* in the common species, and the anterior simple ridges are of a different form.

The strange thing about this little black mouse, which is found at Poschiavo in the Grisons, is that it lives on tobacco. It was first noticed in a tobacco-factory, and was found to make great ravages among the stores of the nicotian weed. When first caught, M. Fatio thought he had possibly got hold of young specimens of the black rat, but subsequently he obtained specimens bearing evident signs of maturity. It does not appear to have suggested itself to M. Fatio's mind, that his *Mus Poschiavinus* may be only a sample of the deleterious effect of indulgence in the noxious herb to which these rodents are addicted. What if this new black mouse is but a stunted race of the black rat? It would furnish an invaluable argument to the anti-tobacconists.

A very pretty coloured plate, representing two Poschiavinian mice helping themselves to cigars, illustrates the description of this species. It is not a little remarkable that an animal should normally feed on tobacco. Monkeys, as is well known to the frequenters of menageries, are exceedingly fond of the end of a cigar, and an elephant has been seen gravely to accept such an offering; but one would have supposed that the amount of nicotine in a pinch of snuff was enough to make a mouse unwell. The indifference of these mice to the toxic action of tobacco, calls to mind the similar indifference on the part of pigeons (rodents are like birds in many things) to the toxic action of opium in the largest doses, as lately noticed by Dr. Weir Michell.

Among the rarer and more interesting forms noticed by M. Fatio as still existing, or as having existed—for he notices the contents of the quaternary deposits in Switzerland—are the Bear (*Ursus arctos*), the Wolf (*Canis lupus*), the Wild Cat (*Felis catus*), the Lynx (*Felis lynx*), the Bouquetin or Ibex (*Capra ibex*), the Chamois (*Capella rufricapra*), and the Stag (*Cervus elaphus*). With regard to this last, it appears that, eighty years since, very fine specimens inhabited the Swiss valleys; now it only appears when driven from the German forests lying to the north; its remains are found in quaternary deposits. The fallow-deer is represented neither in the present nor in the quaternary fauna; the Roebuck, or Chevreuil, is the only cervine species still inhabiting the country. Wolves, lynxes, and wild cats are not uncommon in the forests of the Jura; but the lynx has not been found in the quaternary deposits, which is noteworthy, since Dr. Ransom, of Nottingham, has found it in England in such beds.

The bear is commonest in the Grisons; every year there is some bear-hunting to be done in these wild and elevated valleys. The ibex, though no longer found in the Swiss Alps, occurs in the immediately adjacent territory of Lombardy; where, however, it is now strictly preserved. The ibex of the Alps, of the Pyrenees, of Siberia, and of Crete, each have very distinctive characters, in the direction and length of their horns, but are hardly to be considered as distinct species. Some naturalists, however, distinguish a second species in Spain, as *Ægyceros Hispanicus*, occurring farther south than the so-called *Ægyceros Pyrenaicus*. The domesticated *Capra hircus*, has no doubt largely taken the place of the indigenous ibex; natural hybrids between the two are not uncommon. The industrious Swiss have sometimes exhibited to curious tourists an eccentric specimen of the common goat as a living ibex. M. Fatio mentions such an instance, which may put naturalist travellers on their guard. A specimen presented by the King of Italy may be seen in the Zoological Gardens, Regent's Park. The chamois are still very numerous in Switzerland, though the large herds of eighty and a hundred, which used to be seen in past times, are not now met with. A certain amount of care is exercised now in regard to the time of hunting, and the animals are allowed to breed in security, so that they are on the increase in localities where they had become scarce. M. Fatio mentions an old hunter who boasted of having killed as many as 3,000 chamois.

The Alpine marmot, which is so common and so well known to Alpine tourists, is not the mammal which attains the highest elevation of habitat in Switzerland; another little rodent, the *Arvicola nivalis*, has that distinguished honour, living at a greater altitude than any other European mammal.

Both this species and the marmot live among the oases of rock and herbage which stand out amidst the vast masses of mountain ice. The Bobac marmot does not occur in Switzerland, being confined to the north-eastern districts of Europe. The Alpine marmot inhabits the Carpathians and the Pyrenees, as well as the Alps.

M. Fatio's book is illustrated by eight plates, giving figures of new or rare forms. Synoptical tables of the families and genera are also given, so as to enable the least experienced naturalist to determine with facility the species which may come before him. A second volume, to include the reptiles, batrachia, and fishes, and a third, treating of the birds, are soon to be brought out by the same careful and enthusiastic observer.

E. RAY LANKESTER

OUR BOOK SHELF

Mining Geology.—*Die Lagerstätten der nutzbaren Mineralien.* Von Johann Grimm. (Prague: J. G. Calve).

THE author of this volume is an Oberbergrath, and also Director of the Imperial Mining Academy at Pribram. During the last seventeen years he has from time to time published notices of the mineral veins and other mining features of Transylvania, Hungary, and Bohemia; and he now presents to the public a general treatise or handbook of the useful minerals. His experience has not been wide enough to enable him to write a book that fully justifies the title he has chosen for it, and his acquaintance with the literature of his subject appears to be limited to the German language. But the book is the work of a practical man, is well arranged, and contains much useful information. Fresh illustrations even of well-known facts are always interesting, more especially when they carry with them some little features that are novel. In this respect, mining geologists in this country will find it worth their while to hear what Herr Grimm has to say of the minerals, veins, beds, faults, and other mining features of various parts of the Austrian Empire. A. G.

Practical Astronomy and Geodesy.—*Geographische Ortsbestimmungen mit Hülfstafeln.* 4to. pp. 88. By W. Valentiner. (Leipzig: 1869. London: Williams and Norgate.)

THE purpose of the author was to afford the astronomers engaged in the great European Triangulation tables for facilitating the reduction of the observations made for finding azimuths and the altitude of the pole. The work is, however, of more than a transient merit, for it will probably be of much assistance to our Indian officers engaged in the great trigonometrical survey of the Peninsula, and some of the tabular matter might henceforth in a modified form be well included in works on higher geodetic operations generally.

The author, by differentiating some of the fundamental equations which connect the latitude of a place with the altitude of a heavenly body above the horizon, its declination, azimuth, hour-angle, and parallactic angle, shows the influence which the errors in the observed quantities exert upon those that are dependent upon them, and comes to the conclusion that circumpolar stars are best adapted for azimuth determinations. He especially recommends to the observers engaged in the arc measurement the star *Ursæ minoris*, which is seen at all hours with telescopes of about $1\frac{3}{4}$ to 2 inches aperture, and the succeeding formulæ have been calculated with special reference to that star. Thus, taking the fundamental equations, in which z, a, δ, t, ϕ, are the well-known symbols for zenith distance, azimuth, declination, hour-angle, and latitude respectively, the author obtains by division, transformation, and expansion, and substituting p for $90^\circ - \delta$, the following elegant expression for the azimuth:—

$$a = p \sin t \sec \phi + M \sin 2t + N$$

The values of M and N being essentially dependent on t and ϕ alone; admit of tabulation with t and ϕ as arguments, and are given by the author for all latitudes between 36° north and 64°, this being the extent of the arc to be measured; t is given from ten to ten minutes.

The formulæ for the altitude of the pole are discussed very carefully on the same principles. The whole is the result of much labour, and M. Valentiner well deserves the sincere gratitude of the numerous computers whose work he has facilitated. B. L.

Manual of Physics.—*Lehrbuch der Physik, einschliesslich der Physik der Luft (Meteorologie), des Himmels (Himmelkunde), und der Erde (Physikalische Geographie).* Von Dr. Paul Reis. Erste Hälfte, pp. 256. (Leipzig: Quandt und Händel. 1870.)

THIS is the first half of a treatise on Elementary Physics from a highly scientific point of view. Dr. Reis considers that the principle of the conservation of force—as he puts it, "Die energie des Weltalls ist constant" (the energy of the universe is constant)—is at the root of all science, and that it is possible to deduce a large part of physics as a mathematical consequence of this principle. We confess to a little doubt whether it is advisable to introduce it in this form in the first instance in an elementary text-book. The attempt is one, however, that must be made no doubt at an early date, in some form or other.

The first instalment of the work contains an introduction of considerable length on the elementary ideas at the root of physics—such as space, time, matter, rest and motion, matter and force—the forces which appear in all phenomena, molecular, chemical, cohesion, adhesion, gravitation—and the fundamental axioms of physics, which he gives us in six statements not materially differing from Newton's three laws. After 80 pages out of 500 have been occupied in this way, we confess that we doubt whether sufficient room is left for the adequate treatment of the enormous range of subjects which is to follow. The mechanics of solids, fluids, and gases occupy the author for the next 100 pages, and the last 70 of this first part are given to wave-motions and acoustics.

The book is carefully worked, and full of examples for the student. The new form in which familiar things are presented makes it interesting to those who are acquainted with the subjects it treats of. It appears to be conscientiously brought up to the science of the present day, but we must reserve our opinion as to the question whether it accomplishes the task it proposes to itself, or whether, in its present form, it will be valuable as a text-book till the appearance of the second half, which completes the work. It claims to possess a plan of its own, and it must be estimated according to that claim.

W. J.

Meteorology.—*Die Theorie und Das allgemeine geographische System der Winde.* (Göttingen, 1869. London: Williams and Norgate.)

THE author is an opponent of Dove's school of meteorologists. The facts discussed by him are well known, and far more concisely stated in any recent work on meteorology. The theories founded by the author on those facts are too fanciful, and of his speculations—founded on no facts at all—the least said about them the better.

ON THE PERIODICITY OF THE SOLAR SPOTS

MOST of our readers are aware that the Kew observers, Messrs. De la Rue, Stewart, and Loewy, have for some time past been engaged in investigations, which, as far as they have already extended, go to show that there is an intimate and, as yet, unexplained connection between the configuration of the planets and the position and number of the spots on the sun. This result, which at once seems to land us in a sort of modern astrology, and which is so extraordinary, is, we suppose, on that ground, for we know of no other, questioned by many European astronomers. In this state of the case, no apology is needed, then, for reproducing, from the *Proceedings* of the American Philosophical Society, the results of a recent independent investigation of this subject by Dr. Kirkwood, together with some historical matter of some interest.

Dr. Kirkwood commences by reminding us that the most ancient observations of sun-spots of which we have any record, are those of the Chinese in the year 321 A.D.; the first notice of their detection by Europeans being found in the annals of the Frankish kings. A black spot, according to Adelmus, was seen on the sun's disc, March 17th, 807, and continued visible 8 days. Similar phenomena were again observed from the 28th of May to the 26th of August, A.D. 840. The year 1096 was also signalised by the appearance of spots so large as to be visible to the naked eye. The next date, in chronological order, is that of 1161, when a spot was seen by Averroës. Finally, on the 7th, 8th, and 16th of December, 1590, "a great blacke spot on the sunne," apparently "about the bignesse of a shilling," was observed at sea by those on board the ship "Richard of Arundell." The foregoing are, we believe, the only undoubted instances in which these phenomena were observed previous to the invention of the telescope.

From 1610 to 1750 the sun was frequently observed through instruments of various optical power, and the sparseness, or even the entire absence of spots, during considerable intervals of time, as well as their great number and magnitude at other epochs, were noticed by different astronomers. We come now to a most interesting and most remarkable epoch in the history of solar physics—an epoch in which the periodicity of the spots gradually come out.

The 11-Year Period of Schwabe.—In 1826, Hofrath Schwabe, of Dessau, commenced a series of sun-spot observations, which have been continued without interruption to the present time (1869).

Schwabe has shown a very marked periodicity in the spots; the interval between two consecutive maxima or minima being, according to him, about 10 years. Soon after the announcement of this interesting discovery, Dr. Lamont, of Munich, detected a corresponding decennial period in the variation of the magnetic needle; the epochs of maxima and minima in the latter coinciding with those in the former. These results have also been confirmed by other observers in places quite remote from each other; so that the decennial *magnetic* cycle may be regarded as well established. The equality of this period with that of the solar spots naturally suggested the hypothesis of their intimate relationship. Such a causal connection may be difficult of explanation; the fact, however, is placed beyond doubt by the researches of Wolf and Sabine.* The former, besides carefully observing the sun-spots since 1847, has discussed all accessible recorded observations, both solar and magnetic, bearing on the subject. He had thus ascertained a number of epochs of maxima and minima anterior to those observed by Schwabe,—from all of which he has determined the period of the spots to be 11·11 years. He undertakes to show, moreover, that this period coincides more exactly with that of the magnetic variation than the 10-year cycle of Lamont.

The 56-Year Period.—Besides Schwabe's period of 11 years, Wolf finds a larger cycle of 55 years, in which the solar activity passes through a series of changes. It is not, however, so distinctly marked as the cycle of Schwabe. Its last maximum was about 1837, and that preceding, about 1780.

The 233-Day Period.—Professor Wolf, after carefully discussing his own and Schwabe's observations, claims to have discovered two or three minor periods of solar activity. "By projecting all the results in a continuous curve, he finds in it a series of small undulations succeeding each other at an average interval of 7·65 months," or 233 days.

The 27-Day Period.—The same astronomer thinks he has detected a short period of variation corresponding to the sun's time of rotation with respect to the earth, or about 27 days.

The 584-Day Period.—De la Rue, Stewart, and Loewy, have found a period varying between 18 and 20 months; the mean being about 584 days. Other periods of maxima and minima will probably be detected; but those we have enumerated are perhaps the only ones sufficiently well established to justify any attempt at explanation.

That the solar spots are produced in some way by the planetary disturbance of the photosphere, is now generally admitted. As yet, however, the manner in which this influence is exerted can be little more than matter of conjecture. If the action is analogous to that of the moon on the earth, the relative disturbing power of the different members of the system will be as follows:*

Name.	Mass.	In Aph.	At M. Dist.	In Perih.
Mercury	$\frac{1}{4865751}$ (Encke)	63	111	219
	$\frac{1}{3000000}$ (Leverrier)	102	180	355
Venus	$\frac{1}{401211}$	203	207	211
Earth	$\frac{1}{314760}$	95	100	105
Mars	$\frac{1}{2994790}$	2	3	4
Jupiter	$\frac{1}{1047}$	194	214	236
Saturn	$\frac{1}{3508}$	8	10	12
Uranus	$\frac{1}{24605}$	0	0	0
Neptune	$\frac{1}{18780}$	0	0	0

The connection between the number of sun-spots and the positions of the planets was noticed by Wolf as long since as 1858. In the interesting memoir of De la Rue, Stewart, and Loewy, the causal connection between the positions of Venus and Jupiter and the behaviour of sun-spots seems to be clearly established. An inspection of the Table shows that writers generally have given undue weight to Saturn's influence. Again, although Mercury's action at aphelion is but feeble, and even, at his mean distance, less than that of Venus or Jupiter, his perturbing power at *perihelion* is the greatest of all planets—a fact which certainly demands consideration in any theory which refers the origin of solar spots to planetary agency. After giving the subject much study and attention, Dr. Kirkwood deems it impossible, *without the introduction of any modifying cause*, to establish a general correspondence between the different sun-spot periods and those of regularly recurring planetary configurations.

But the hypothesis that a particular portion of the sun's surface is more favourable to spot formation—or, in other words, more susceptible to planetary influence—than others, will, he believes, obviate all difficulty. Is

* These magnetic variations, which will not be discussed in the present paper, are mentioned to give completeness of view to the phenomena under consideration. It is also worthy of remark that the Aurora Borealis is believed to exhibit a corresponding periodicity. [We believe that Sir E. Sabine was the first to remark the connection between sun-spots and magnetic disturbances.—ED.]

* The table is derived from the formula $\delta = \frac{m}{a^3}$, where δ represents the disturbing power of a planet, m its mass, and a its distance.

there, then, any independent probability of the truth of this hypothesis? It is well known that the formation of spots occurs chiefly between particular parallels of *latitude*, and that the numbers are greater in the northern than in the southern hemisphere. It seems, therefore, at least not improbable that a like difference may exist in regard to *longitude*. "Sömmering directs attention to the fact, that there are certain meridian belts on the sun's disc, in which he had never observed a solar spot for many years together." * Buys-Ballot, of Utrecht, has found, from an elaborate discussion of a great number of meteorological observations, that there is a short period of variation in the amount of solar heat received by our planet; the period from maximum to maximum coinciding, at least approximately, with that of the sun's rotation with respect to the earth. Sir William Herschel also believed that one side of the sun, on account of some peculiarity in its physical constitution, was less adapted to radiate light and heat than the other.

On Dr. Kirkwood's hypothesis, the sun-spot period would be equal to the interval between two conjunctions of the disturbing planets on the heliographic meridian (designated by M) of that part of the surface most susceptible to their influence. It would depend, therefore, on the ratio of the sun's period of rotation to the interval between two consecutive conjunctions of such planets. Or, as Mercury's influence is extremely variable, a maximum would be produced by this planet's perihelion passage, when the most susceptible part of the sun's surface had the same, or nearly the same, heliocentric longitude. In order, then, to test this hypothesis, we must first inquire what is the most probable period of the sun's rotation?

On account of the *proper* motion of the solar spots, the time of the sun's rotation as determined by their *apparent* motion across the disc, varies from about 25 to 29 days. The *proper* motion of the spots has recently been discussed with great labour and ability by Professor Spörer, of Anclam, and Mr. Carrington, in England, who have shown conclusively that the rapidity of movement varies regularly with the latitude. The equatorial portions have the greatest angular velocity; in other words, the proper motion of the spots is in a direction contrary to that of the sun's rotation. The formulæ by which the astronomers named expressed the law for the dependence of the sun's apparent period of rotation on the latitude are as follows:—

According to Carrington, $\xi = 865' - 165' \sin \frac{7}{4} l$. . . (1)

" " Spörer, $\xi = 16{\cdot}8475° - 3{\cdot}3812° \sin (41° 13' + l,)$ . . . . (2)

where ξ is the arc described in a solar day. The true time of rotation is supposed to be that indicated by an equatorial spot; and on this assumption, (1) gives

$$P = 24{\cdot}9711 d. = 24 d.\ 23 h.\ 18 m.\ 23 s. \quad . . . . . . \quad (3)$$

or, (2) gives

$$P = 24{\cdot}62447 d. = 24 d.\ 14 h.\ 59 m.\ 0 s. \quad . . . . . . \quad (4)$$

The true value is probably between the results here given.

But will this modifying element in the theory of planetary action afford a satisfactory explanation of the periodic recurrence of maxima and minima of solar spots? Let us consider.

(*a.*) *The* 11-*Year Cycle.*—The anomalistic period of Mercury is 87·9702*d.*, and

$$87{\cdot}9702 d. \times 46 = 4046{\cdot}6292 d. = 11{\cdot}077 y. = T_1 \quad . . \quad (5)$$

This is very nearly equal to Wolf's value of the cycle, and agrees at least equally well with recorded facts.†

Again, $\frac{T_1}{163} = 24{\cdot}82594 d. = 24 d.\ 19 h.\ 49 m.\ 21 s.$ . . . (6)

which is nearly a mean between Spörer's and Carrington's values of the sun's period of rotation. With this, therefore, as the time of the sun's axial revolution, we have 46 times the period of Mercury—equal to 163 times that of the sun's rotation. The recurrence of maxima at mean intervals of 11·077 years would thus be accounted for.* Again, the epochs at which sun-spots were seen before the invention of the telescope may be presumed, with much probability, to have been nearly coincident with the maxima epochs of Schwabe's cycle. Now, it is a remarkable fact that all of those dates, except perhaps the last, harmonise with the value which we have adopted for Schwabe's period of variation. Thus:

From	321, A.D.	to	1860,	we have	139	periods of	11·072 +	yrs. each.
"	321	"	807	"	44	"	11·045	"
"	807·22	"	840·5	"	3	"	11·093	"
"	840·5	"	1096	"	23	"	11·109	"
"	1096	"	1161	"	6	"	10·833	"
"	1161	"	1590·9	"	39	"	11·024	"
"	1590·9	"	1750·0	"	14	"	11·367(?)	"
"	1750·0	"	1829·0	"	7	"	11·286	"
"	1829·0	"	1860·5	"	3	"	10·500	"

The variability of the period will be hereafter considered.

(*b.*) *Wolf's Cycle of* 56—57 *Years.*—The synodic revolution of Mercury is 115·87748*d.*, and

$$115{\cdot}87748 d. \times 177 = 20510{\cdot}31396 d. = 56{\cdot}15324 y. = T_2 \ (7)$$

In this period the line of conjunction of Mercury and the earth advances 56·15324 revolutions. Now,

$$\frac{T_2}{826{\cdot}15324} = 24{\cdot}82628 d. = 24 d.\ 19 h.\ 49 m.\ 50 s. \quad . . . \quad (8)$$

This value of the sun's period of rotation differs from that in (6) by only 29 seconds. Adopting it, therefore, we find that Mercury and the earth will be in conjunction on the same heliographic meridian at regularly recurring epochs of 56 years and 56 days.

(*c.*) *The* 233-*Day Period.*—The mean interval between the consecutive conjunctions of Venus and Jupiter is 236·992*d.* The close agreement of these periods leaves little room to doubt that the latter is the true period of spot variation.

(*d.*) *The* 27-*Day Period.*—This is at once satisfactorily accounted for.

(*e.*) *The* 584-*Day Period.*—The identity of this period with that of the synodic revolution of Venus has already been indicated by De la Rue, Stewart, and Loewy.

Remarking that Dr. Kirkwood advances other facts in support of his argument, we pass at once to his conclusions.

1. A connection between the behaviour of sun-spots and the configurations of certain planets has been placed beyond reasonable doubt.

2. The theory, however, of spot formation by planetary influence is encumbered with anomalies and even inconsistencies, unless we admit the co-operation of a modifying cause.

3. The hypothesis that a particular part of the solar surface is more susceptible than others to planetary disturbance is rendered probable by the observations of different astronomers.

4. The 11-year cycle of spot variation is mainly dependent on the influence of Mercury.

5. The marked irregularity of this period from 1822 to

* Humboldt's Cosmos, vol. iv., p. 378.

† The following astronomical cycles are also nearly equal to this period of variation:—

1. 18 periods of Venus = 11·074*y.*	4. $17 t_1 = 11{\cdot}030 y.$
2. 35 syn. per. of Mer. = 11·104	5. $28 t_2 = 11{\cdot}082$
3. 1 period of Jupiter = 11·860	6. $45 t_3 = 11{\cdot}063$

where t_1 = the syn. per. of Venus with respect to Jupiter; t_2 = syn. per. of Mercury with respect to Venus; and t_3 = that of Mercury with respect to Jupiter.

* It is not probable that Mercury is on the meridian M precisely at the epoch of perihelion passage. It is only necessary to suppose this coincidence to occur when the planet is *near* the perihelion point. Even at the distance of 20° the diminution of the disturbing power would be extremely small.

1867, is in a great measure due to the disturbing action of Venus.

6. Wolf's 56-year cycle is determined by the joint action of Mercury and the Earth. And,

Finally, *the hypothesis proposed accounts, as we have seen, for all the well-defined cycles of spot-variations.*

NOTE ON THE CORRELATION OF COLOUR AND MUSIC

WHILST engaged in the preparation of an article on the Analogy of Light and Sound for the current number of the *Quarterly Journal of Science*, I was led to examine the grounds of the frequently-assumed relationship between the colours of the solar spectrum and the notes of the musical scale. It is well known that Newton found a connection between the relative spaces occupied by each colour and the relative vibrations of the notes of the scale. But this, I presume, cannot be more than an accidental coincidence. The common basis of comparison is obviously the ratio of the wave-lengths in the two cases. Although according to the tables given in text-books no satisfactory connection can be found, yet many considerations appear to justify a stricter comparison of these natural scales of colour and sound.

The ratio of wave-lengths of the two extremes of the spectrum is usually taken as 1 : 0.57, or corresponding to the interval of a seventh in music.

But this statement is only true when a glass prism is employed; the ultra-violet rays are then suppressed. Substituting quartz for glass, light of higher refrangibility is seen: the limits of the spectrum can thus be extended from the solar line A to the solar line L.* Now, the wave-length of A (according to Ångström) is 760 millionths of a millimetre, and the wave-length of L (according to Mascart) is 381 millionths of a millimetre, or as the ratio of 1 : 0·50, exactly corresponding to the interval of an octave in music.

The ratios of the extreme colours of the spectrum and the extreme notes of an octave are coincident.

The next object is to compare the ratio of wave-lengths giving rise to the intermediate colours of the spectrum with the ratio of wave-lengths giving rise to the intermediate notes of the scale.

The most careful localisation of the colours of the spectrum with which I am acquainted is that by Prof. Listing.† In his recent memoir on the wave-lengths of the spectra of the metals, M. Thalén gives Prof. Listing's estimation of the extreme limits of each colour as follows:‡

TABLE I.

Name.	Limiting Wave lengths in ten-millionths of a millimetre.
Red	7234 to 6472
Orange	6472 to 5856
Yellow	5856 to 5347
Green	5347 to 4919
Blue	4919 to 4555
Indigo	4555 to 4241
Violet	4241 to 3967

Taking the *mean* of the two limits to represent the average wave-length of each colour, we have the following series:—

TABLE II.

Name.	Mean wave-lengths in ten-millionths of a millimeter.	Ratio.
Red	6853	100
Orange	6164	89
Yellow	5601	81
Green	5133	75
Blue	4737	69
Indigo	4395	64
Violet	4104	60

* Mr. Crookes informs me that on favourable occasions he has even seen beyond L.

† Poggendorff's "Annalen," 1868, vol. 131, p. 564.

‡ Trans. Roy. Soc. Upsal, third series, vol. vi.: also Annales de Chimie et de Physique, October 1869, and NATURE, No. 2.

Calling the wave-length of the mean red 100, the numbers in the third column express the corresponding ratios of the mean wave-lengths of the other colours.

In the next table is given the similar data as regards sound. The *first* column contains the names of the musical notes; the *second* their actual wave-lengths starting from the middle C; the *third* column gives the relative wave-lengths in fractions of C; and the *fourth*, the ratio without fraction, C being taken as 100.

TABLE III.

Name.	Wave-length in inches.	Ratio of wave-lengths.	
C	52	1 or	100
D	46⅓	8/9	89
E	42	4/5	80
F	39	3/4	75
G	35	2/3	67
A	31	3/5	60
B	27½	8/15	53
C_2	26	1/2	50

Placing together the ratio given in the last columns of Tables II. and III., the following remarkable correspondence comes out:—

TABLE IV.

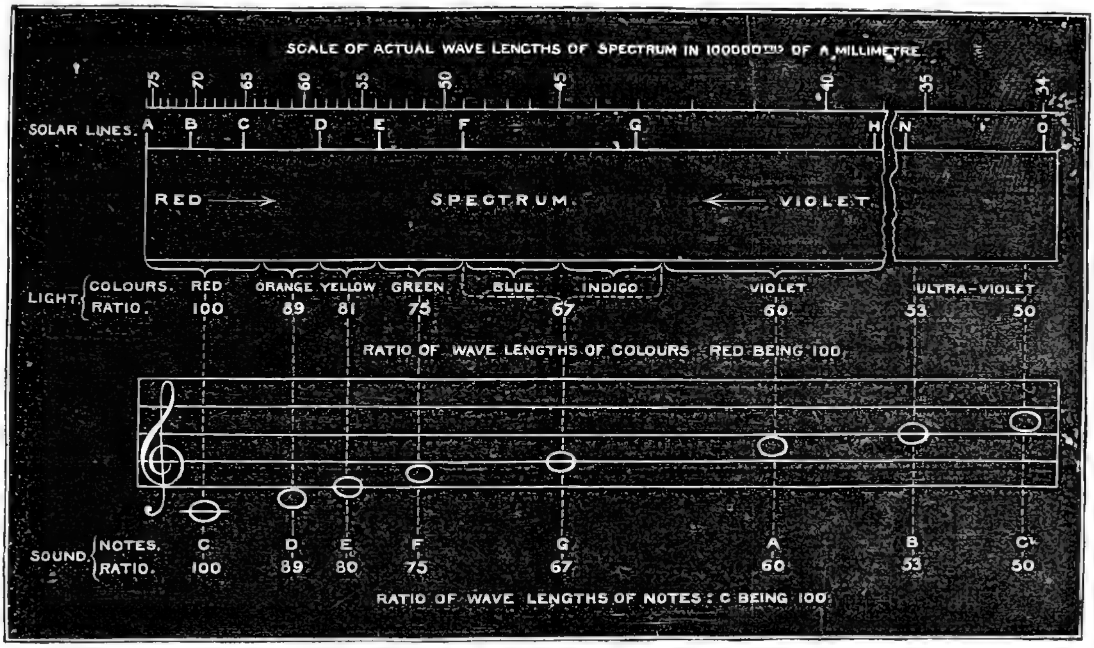
Colour.	Ratio.	Notes.	Ratio.
Red	100	C	100
Orange	89	D	89
Yellow	81	E	80
Green	75	F	75
Blue . 69 } Indigo 64 } mean,	67	G	67
Violet	60	A	60
[Ultra-Violet	53]	B	53
[Obscure	50]	C_2	50

Assuming the colour *red* to correspond to the note C, then we find *orange* exactly corresponds to D; *yellow* is almost exactly the same as E; and if we take the wave length of E from observation and not from theory, we have 52 : 42 = 100 : 80·8, a still closer approximation to yellow. The ratio of green is identical with that of F. *Blue*, however, does not correspond to G, nor *Indigo* to A; but blue and indigo are practically one colour in the spectrum,—the line of demarcation, difficult to fix between any other colours, is impossible to be established here. I think, therefore, I am justified in putting them together, and if we do so we find their mean ratio exactly corresponds to G. Violet now exactly corresponds to the ratio given by A. Here all distinct colour ends. But beyond this region Sir John Herschel detected a lavender colour, which finally shades away into a dusky grey. The wave-length of this ultra-violet region is not given by Prof. Listing; hence the ideal position is calculated and inserted in the table within brackets. As the lower C is placed at the *mean* red, the upper C would then correspond to a region in the spectrum altogether obscure: viz., at the solar line O. But as already stated above, if we place the lower C at the *extreme* red, then its higher octave would fall on the line L, or within the range of vision.* The great difference of position thus produced at the violet extremity by a slight movement at the other end of the spectrum, is caused by the crowding together of the colours at the red end. This is shown, together with the correspondence of the ratios of sound and colour, in the accompanying diagram.

The musical scale is thus literally a rainbow of sound. Harmony in colour and music may thus, probably, be found to have a common physical basis. There are many indications that this is the case. For example, the juxtaposition of two colours nearly alike is bad, and so also two adjacent notes of the scale sounded together produce discord. The succession of colours in the spectrum

* A suggestion, made, I believe, by Sir J. Herschel, that the colours of the spectrum would probably repeat themselves if we could see beyond the lavender, both supports, and gains support from, this analogy.

and of notes in the scale is the most harmonious that can be found; any disturbance of the order in either case makes the succession less pleasant. Discord or harmony may be the result of the combination of certain notes, and so also with colours. A pleasant effect is produced by the juxtaposition of red and blue, or of red and green: the former combination corresponds to the ratios given by C and G, or the harmonious interval of a fifth; the latter combination corresponds to C and F, or the slightly less pleasant interval of a fourth.



This apparent correlation of music and colour suggests many other speculations, but at present I would only venture to submit the foregoing considerations to the opinion of physicists.

W. F. BARRETT

THE SLAVONIANS IN TURKEY

A VERY careful and complete account of the result of the latest researches in the ethnology and geography of the Turkish Slavonians is given in the new number of Petermann's *Mittheilungen* by Professor Francis Bradashka, of Agram. The author is himself a member of that branch of the great Slavonic race to which the Turkish Slavonians belong, and evidently takes a strong political as well as scientific interest in their position; but his work is on the whole singularly free from political bias, and may be safely referred to by those who desire to increase their knowledge of the subject. The facts of Turkish ethnology are scattered in a variety of books and articles in periodicals, most of which are very difficult of access, and the only place where they could hitherto be found in a condensed form is an appendix to the fourth number of the *Mittheilungen* by M. Lejean, published in 1861. M. Lejean's paper, however, though full of valuable information and accompanied by an excellent ethnological map, gives little more than a bird's-eye view of the subject; and Professor Bradashka, besides correcting some important errors in it, has added much statistical and geographical detail which throws a new light on some of the most interesting questions of Turkish ethnology. One of these is the origin and development of the Albanian (Shkipetar) settlements in Turkey. Herr von Hahn, one of the best known authorities on this subject, holds that the Shkipetars were the original inhabitants of old Servia and the districts between Albania and the Vardar river; and that while these countries were under the Servian rule, the Shkipetars were compelled by their conquerors to take refuge in the hills, whence they afterwards descended when the Servians were beaten in their turn by the Turks. Professor Bradashka, on the other hand, shows, as we think, conclusively, that the countries in question were originally inhabited by Servians, and that the Shkipetars who now occupy them are the descendants of immigrants from Albania who settled there after the break-up of the Servian Empire. A very interesting and important fact brought out by the Professor in connection with this subject is, that the Shkipetars are gradually edging out the Slavonians from many districts which were formerly occupied almost exclusively by the latter race. This is especially observable in the towns. In Vuchitrn, Novo Brdo, and Dyakova, nearly all the inhabitants are now Shkipetars; and in Matochia, the ancient residence of the Servian kings, there are more Shkipetars than Servians. Old Servia was almost entirely Servian when Shafazyk wrote in 1849; it is now predominantly Shkipetar. There are also now Shkipetar settlements, not mentioned by M. Lejean, at the mouth of the Maburitza, and on the eastern and western shores of the lake of Scutari (Skodra).

The acceptance of the Mahometan religion by many of the Slavonians in Turkey has led to great confusion as to the Turkish population of the country. Some unscrupulous partisans of the Ottoman rule have not hesitated to state that there are six millions of Turks in European Turkey—an absurd exaggeration which can only impose on people who are totally ignorant of the facts. Professor Bradashka agrees with the best authorities in estimating the Turkish population at under a million, and points out a singular blunder made by M. Lejean, in his otherwise very accurate map, as to the Turkish inhabitants of Bulgaria. According to his map the whole of Eastern Bulgaria, or about a third of the whole province, is Turkish. This the Professor shows to be impossible, for there are only 375,000 Turks in the province, most of whom reside in the towns in all parts of Bulgaria, while the total population is between four and five millions. Evidently M. Lejean reckoned among his Turks the Mahometan Bulgarians, who reside for the most part in the eastern districts.

The whole of this valuable little pamphlet is contained in seventeen pages, and its usefulness is considerably increased by a good map. The map embraces all the country occupied by the Southern Slavonians, from Galicia to the Ægean Sea, and seems to be very accurate; but it is a pity that Dr. Petermann did not leave out the shading of the mountains. This, in a map on such a small scale, is totally useless for topographical purposes, and only occupies space which would be much more profitably employed by the insertion of more names of places, besides obscuring the names which already exist. The districts inhabited by Slavonians are painted green, thus showing at a glance their geographical position. It would have been better to distinguish by a different colour the Bulgarians—who, like the Russians, are Slavonians grafted on a Turanian stock, from the pure Slavonians, such as the Servians, Croats, and Ruthenians.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Government Aid to Science

I VENTURE to hope that you will allow me space in your columns to express opinions on this subject which are not popular with scientific men, and which are evidently opposed to your own views as indicated in your recent article on Science Reform.

The public mind seems now to be going mad on the subject of education; the Government is obliged to give way to the clamour, and men of science seem inclined to seize the opportunity to get, if possible, some share in the public money. Art education is already to a considerable extent supplied by the State,—technical education (which I presume means education in "the arts") is vigorously pressed upon the Government,—and Science also is now urging her claims to a modicum of State patronage and support.

Now, sir, I protest most earnestly against the application of public money to any of the above specified purposes, as radically vicious in principle, and as being in the present state of society a positive wrong. In order to clear the ground let me state that, for the purpose of the present argument, I admit the right and duty of the State to educate its citizens. I uphold national education, but I object absolutely to all sectional or class education; and all the above-named schemes are simply forms of class education. The broad principle I go upon is this,—that the State has no moral right to apply funds raised by the taxation of all its members to any purpose which is not directly available for the benefit of all. As it has no right to give class preferences in legislation, so it has no right to give class preferences in the expenditure of public money. If we follow this principle, national education is not forbidden, whether given in schools supported by the State, or in museums, or galleries, or gardens, fairly distributed over the whole kingdom, and so regulated as to be equally available for the instruction and amusement of all classes of the community. But here a line must be drawn. The schools, the museums, the galleries, the gardens, must all alike be *popular* (that is, adapted for and capable of being fully used and enjoyed by the people at large), and must be developed by means of public money to such an extent only as is needful for the highest attainable *popular* instruction and benefit. All beyond this should be left to private munificence, to societies, or to the classes benefited, to supply.

In art, all that is needed only for the special instruction of artists, or for the delight of amateurs, should be provided by artists and amateurs. To expend public money on third-rate prints or pictures, or on an intrinsically worthless book, both of immense value on account of their rarity, and as such of great interest to a small class of literary and art amateurs and to them only, I conceive to be absolutely wrong. So, in science, to provide museums such as will at once elevate, instruct, and entertain all who visit them is a worthy and a just expenditure of public money; but to spend many times as much as is necessary for this purpose in forming enormous collections of all the rarities that can be obtained, however obscure and generally uninteresting they may be, and however limited the class who can value or appreciate them, is, as plainly, an unjust expenditure. It will, perhaps, surprise some of your readers to find a naturalist advocating such doctrines as these; but though I love nature much I love justice more, and would not wish that any man should be compelled to contribute towards the support of an institution of no interest to the great mass of my countrymen, however interesting to myself.

For the same reason I maintain that all schools of art or of science, or for technical education, should be supported by the parties who are directly interested in them or benefited by them. If designs are not forthcoming for the English manufacturer, and he is thus unable to compete with foreigners, who should provide schools of design but the manufacturers and the pupils who are the parties directly interested? It seems to me as entirely beyond the proper sphere of the functions of the State to interfere in this matter as it would be to teach English bootmakers or English cooks at the public expense in order that they may be able to compete with French *artistes* in these departments. In both cases such interference amounts to protection and class legislation, and I have yet to learn that these can be justified by the urgent necessity of our producing shawls and calicoes, or hardware and crockery, as elegantly designed as those of our neighbours. And if our men of science want more complete laboratories, or finer telescopes, or more expensive apparatus of any kind, who but our scientific associations and the large and wealthy class now interested in science should supply the want? They have hitherto done so nobly, and I should myself feel that it was better that the march of scientific discovery should be a little less rapid (and of late years the pace has not been bad), than that Science should descend one step from her lofty independence and sue *in formâ pauperis* to the already overburthened taxpayer. So if our mechanics are not so well able as they might be to improve the various arts they are engaged in, surely the parties who ought to provide them with the special education required are the great employers of labour, who by their assistance are daily building up colossal fortunes; and that great and wealthy class which is, professionally or otherwise, interested in the constructive or decorative arts.

I maintain further, not only that the money spent by Government for the purposes here indicated is wrongly spent, but also that it is in a great measure money wasted. The best collectors are usually private amateurs, the best workers are usually home students or the employés of scientific associations, not of governments. Could any Government institution have produced results so much superior to those produced by our Royal Institution, with its Davy, Faraday, and Tyndall, as to justify the infringement of a great principle? Would the grand series of scientific and mechanical inventions of this century have been more thoroughly and more fruitfully worked out, if Government had taken science and invention under its special patronage in the year 1800, and had subjected them to a process of forcing from that day to this? No one can really believe that we should have got on any better under such a *régime*, while it is certain that much power would have been wasted in the attempt to develop inventions and discoveries before the age was ripe for them, and which would therefore have inevitably languished and been laid aside without producing any great results. Experience shows that public competition ensures a greater supply of the materials and a greater demand for the products of science and art, and is thus a greater stimulus to true and healthy progress than any Government patronage. Let it but become an established rule that all institutions solely for the advancement of science and art must be supported by private munificence, and we may be sure that such institutions would be quite as well supported as they are now, and I believe much better. If they were not, it would only prove more clearly how unjust it is to take money from the public purse to pay for that which science-and-art-amateurs would very much like to have, but are not willing themselves to pay for.

The very common line of argument which attempts to prove the wide-spread uses and high educating influences of art and of science, are utterly beside the question. Every product of the human intellect is more or less valuable; but it does not therefore follow that it is just to provide any particular product for those who want it, at the expense of those who either do not want, or are not in a condition to make use of it. Good architecture, for instance, is a very good thing, and one we are much in want of; but it will hardly be maintained that architects should be taught their profession at the public expense. The history of old china, of old clothes, or of postage stamps, are each of great interest to more or less extensive sections of the community, and much may be said in each case to prove the value of the study; but surely no honest representative of the nation could vote, say, the moderate sum of a million sterling for three museums to exhibit these objects, with a full staff of beadles, curators, and professors at an equally moderate expenditure of £10,000 annually, and a like sum for the purchase of specimens. But if we once admit the right of the Government to support institutions for the benefit of any class of students or amateurs however large and respectable, we adopt a principle which will enable us to offer but a feeble resistance to the claims of less and less extensive interests whenever they happen to become the fashion.

If it be asked (as it will be) what we are to do with existing institutions supported by Government, I am at once ready with an answer. Taking the typical examples of the National Gallery and the British Museum, I maintain that these institutions should be reorganised, so as to make them in the highest degree entertaining and instructive to the mass of the people;—that no public money should be spent on the purchase of specimens, but what they already contain should be so thoroughly cared for and utilised as to make these establishments the safest, the best, and the most worthy receptacles for the treasures accumulated by wealthy amateurs and students, who would then be ready to bestow them on the nation to a much greater extent than they do at present. From the duplicates which would thus accumulate in these institutions, the other great centres of population in the kingdom should be proportionately supplied, and from the Metropolitan centres trained officers should be sent to organise and superintend local institutions, such a proportion of their salaries being paid by Government as fairly to equalise the expenditure of public money over the whole kingdom, and thus not infringe that great principle of equality and justice which I maintain should be our guide in all such cases.

This communication will doubtless call forth much opposition, but I trust it will also elicit the support of some of those eminent scientific men, who I know hold similar general views, and who are so much better able than I am to explain and support them.

ALFRED R. WALLACE

Kant's View of Space

IN the very remarkable contribution by Professor Sylvester, (NATURE, No. 9) this sentence occurs: "It is very common, not to say universal, with English writers, even such authorised ones as Whewell, Lewes, or Herbert Spencer, to refer to Kant's doctrine as affirming space to be a 'form of thought' 'or of the understanding.' This is putting into Kant's mouth (as pointed out to me by Dr. C. M. Ingleby) words which he would have been the first to disclaim."

It is not on personal grounds that I wish to rectify the misconception into which Dr. Ingleby has betrayed Professor Sylvester. When objections are made to what I have written, it is my habit either silently to correct my error, or silently to disregard the criticism. In the present case I might be perfectly contented to disregard a criticism which any one who even glanced at my exposition of Kant would see to be altogether inexact; but as misapprehensions of Kant are painfully abundant, readers of Kant being few, and those who take his name in vain being many, it may be worth while to stop *this* error from getting into circulation through the channel of NATURE. Kant assuredly did teach, as Professor Sylvester says, and as I have repeatedly stated, that space is a form of intuition. But there is no discrepancy at all in also saying that he taught space to be a "form of thought," since every student of Kant knows that intuition without thought is mere sensuous *impression*. Kant considered the mind under three aspects, Sensibility, Understanding, and Reason. The *à priori* forms of Sensibility, which rendered Experience possible, were Space and Time: these were forms of thought, conditions of cognition. It was by such forms of thought that he reoccupied the position taken by Leibnitz in defending and amending the doctrine of innate ideas, namely, that knowledge has another source besides sensible experience,—the *intellectus ipse*.

While, therefore, any one who spoke of space as a "form of the understanding" would certainly use language which Kant would have disclaimed, Kant himself would have been surprised to hear that space was not held by him as a "form of thought."

January 3 GEORGE HENRY LEWES

Transcendent Space

As my name has been mentioned by Prof. Sylvester, at p. 238 of NATURE, in connection with this subject, I must ask you to allow me to make a brief remark thereupon. With the late Prof. Donkin I have not the least doubt as to this notion being "only a disguised form of algebraical formulisation." I observe that Prof. Sylvester, while *hypothetically* mentioning his own blindness, backs up his belief by the names of seven great mathematicians, who are *hypothetically* assumed to have "an inner assurance of the reality" of space of four dimensions. A roll-call of great names is no evidence of a strong position, and in the present case the citation is somewhat unfortunate. My old friend Dr. Salmon, who is one of the seven mathematicians cited, would, I am sure, disclaim any such "inner assurance." Without any breach of confidence I may quote his own reply to a question which I put to him long before the delivery of Prof. Sylvester's address. It was in these words: "I do not profess to be able to conceive *affairs* of four dimensions. . . . I advise you to believe whatever Sylvester tells you, for he has the power of seeing things invisible to ordinary mortals."

It would be more satisfactory to unbelievers like myself if the gifted author of the address were to assure the world that he had an insight into, or clear conception of, this transcendent space, According to my own view, *space cannot have more or less than three dimensions;* but if a form of extension having four dimensions were once revealed to us, tridimensional space (in which we now "live and move and have our being," and which is for us one of *two only universal forms of sense*), together with all that it contains, would become zero, and thenceforward we should only be able to conceive tridimensional space as a limit to the finite contents of quadridimensional space. Nay, more, the new space would be inevitably fatal to the law of gravitation, which is a transcendental deduction from the three only dimensions of space. Of course I see plainly enough that the Hamiltonian theory of "quinaries" (which is at present concretely interpretable only in time, *i.e.* as applied to sets of five points in time) might be developed into a rectorial system of *Quinions*, where the four symbols of operation would express the rotation of a straight line about four symmetrical axes; but the form of extension required for the interpretation of such a system is not only inconceivable, but is seemingly opposed to the very intellect itself.

Ilford, January 8 C. M. INGLEBY

The Cyclone

IN answer to the request of your correspondent, F.R.A.S., of Plymouth, in No. 8 of NATURE, I venture to send the following observations of the storm of Dec. 16, in West Suffolk. The barometer is reduced to sea level and 32° Fahr.

Dec. 16—2 p.m.: bar. 29·598, having fallen about ·15 since the morning: air temp. 44° max. of day hours; wind fresh, S., sky overcast.

5 p.m.: bar. 29·334, air temp. 42°; wind S.S.E. high, with heavy rain, which had begun about 4.

10 p.m.: bar. 28·821, a fall of ·5 in 5 hours; wind S.W. gale; rain stopped. The rainfall amounted to ·53 in. During this gale the temp. rose to 54°. The wind veered, at times blowing with great violence, attaining its maximum a little before 11 p.m. Direction nearly W. After 11 the force began to abate.

12 mid.: bar. 29·031, a rise of ·2; wind high from W.N.W.

Dec. 17.—Bar. 29·625, wind still very fresh from W.N.W.

The movement of the barometer from 2 to 10 p.m. of 16th, was 0·78 in., and on morning of 17th the pressure returned to the same point as on 2 p.m. of 16th. The maximum of the wind force occurred a little after the minimum of air pressure, when barometer was rising (compare Capt. Toynbee's "Isobaric Curves" pp. 6, 7). The veering of the wind shows that the track of the centre of the storm passed to the N. of this latitude (52° N.) M.A.

Haverhill, Suffolk, Dec. 28

I ONLY noticed this morning a request of one of your correspondents, who wishes some one in the north or east of England to give an account of the storm which occurred on the 17th instant, as he considers it a remarkable instance of a cyclone.

I enclose the hourly readings of the barograph and anemograph at Stonyhurst during the storm that occurred on the 17th and 19th, but I doubt whether they will be found very confirmatory of the supposed nature of the storm. The fall and rise of the barometer agree remarkably with the complete circuit through which the wind veered from W.S.W. through S. and N. back to W.S.W., but the storm, as is usually the case, began about four hours after the barometer had passed its minimum: the storm lasted 14 hours 30 minutes. The rainfall was moderate. I have given you the readings on the 16th on account of the interesting coincidence between the veering completely round of the wind, and the gradual fall and rise of the barometer. On the 19th a greater storm occurred, but with a less marked connection between barogram and anemogram.

Stonyhurst, Whalley, Dec. 29 S. J. PERRY

The Suez Canal

SINCE I last addressed you I have had an opportunity of inspecting the Suez Canal under the most favourable circumstances. After a careful personal examination, and having heard the various opinions of others differing in every conceivable respect, I think that, considering all things, M. de Lesseps and his staff have much cause to feel proud of the success they have attained. To return to my previous letter, I may say, without fear of any objections which may hereafter be raised, that not only do I think the suggestions I then made are sound and practical, but that to carry them out would be most economical to the shareholders of the Canal, while to the Egyptian Government it would add probably 25 per cent. to the land revenue, by reclaiming a vast extent of desert that only requires water to make it most productive.

From inquiries also into the land settlement question of Egypt, I believe that this project of raising the canal-levels by fresh water could be carried out without any complaint being raised by the cultivators, who do the earth work, and would be repaid by title-deed to the land to be reclaimed; for, after all, the work would not be great, simply widening the present sweet-water canal some 30 metres. By a set of locks just before entering Lake Ballah from the south, and a similar set of locks before entering the bitter lakes from the north, the surface level of the water in Lake Timsah could be held up 2½ metres. Thus much of the expensive deepening and widening of the canal would be saved, which is all the more important as it is in this division of the canal that rock has been found.

It may be said that the Nile could not supply sufficient water, but with a weir or "anicut" across the Nile at Cairo, where stone is plentiful, not only could a supply of water be obtained, but I believe the whole system of irrigation in Egypt would be greatly improved.

So much for the interests of the shareholders and the people of Egypt, but what would the ship captains say at being detained by having to pass two sets of locks?

In reply to this objection I may say, that as the passage from the Timsah Lake takes seven or eight hours of daylight either way, half an hour's detention is of no consequence, for all sea-going ships must remain a night in Lake Timsah; so that as the ship would thus be some eighteen hours in *fresh* water, the marine animals and weeds would most probably all drop off the ship's bottom, and so the hour's loss of time by lockage would be more than compensated by the days saved on the voyage.

I have not time at present to speak of the deposits at Port Said, or the currents at the Suez end of the Canal, but will address you on these interesting questions on some future occasion after I arrive in India. In conclusion, I must add, that the Canal authorities have one and all been most civil and obliging, showing and explaining everything.

T. LOGIN, C.E.
Late of the Ganges Canal

P. & O. Co.'s Ship *Nubia*,
Suez, November 29, 1869

NOTES

PROFESSOR HELMHOLTZ, of Heidelberg, has been elected a corresponding member of the Physical Section of the Paris Academy of Sciences in the room of M. Marianini. Votes:—Helmholtz 37, Kirchhoff 3, Sir W. Thomson 2, Ångström 1, Mayer 1. At the same meeting the Secret Committee appointed to nominate candidates for the place of corresponding member vacant owing to the death of M. Matteucci, announced the following list:—In the first rank,—M. Mayer of Heilbronn. In the second rank,—M. Ångström of Upsala, M. Billet of Dijon, M. Dove of Berlin, Mr. Grove of London, Mr. Henry of Philadelphia, M. Jacobi of St. Petersburg, Mr. Joule of Manchester, M. Kirchhoff of Heidelberg, M. Riess of Berlin, Mr. Stokes of Cambridge, Sir W. Thomson of Glasgow, Mr. Tyndall of London, M. Volpicelli of Rome. The election takes place at the next meeting of the Academy.

HER MAJESTY has been pleased to signify her desire that the Historical and Archæological Association of Ireland be henceforth called the Royal Historical and Archæological Association of Ireland, and that the members of the Association be styled "Fellows."

AT the meeting of the Paris Academy held on the 29th ult., the death of M. Erdmann, the Swedish geologist, was announced. M. Erdmann was chairman of the commission for the Geological Survey of Sweden.

MR JAMES NICOL and Dr. G. Dickie, the Professors of Natural History and Botany in the University of Aberdeen, have addressed a joint letter to the *Aberdeen Free Press*, defending the science-teaching of the university from some remarks made by Professor Geddes in his pamphlet on Classical Education in the North of Scotland. They show that the students have given the greater part of their school life to the classics; that the time allowed for scientific work at the university is only one-sixth of that assigned to classical studies; that the 3,000*l.* a-year given as bursaries were until recently confined solely (and still are chiefly) for merit in classics; and that a considerable sum is devoted to Classical prizes, whilst the highest honours in Natural Science have been rewarded for the last two years with the magnificent sum of 10*l.* Notwithstanding these disadvantages, and in spite of the deliberate endeavour of the commissioners appointed "for the advancement of religion and learning in the universities" to suppress the teaching of Natural Science in the university, Professors Nicol and Dickie are able to point with justifiable pride to the list of honours in Natural Science, a list "including the names of the two Murray scholars, the chief prize now given for general proficiency in the university."

WE have received the report of the Council of the Birmingham Midland Institute, presented at the annual meeting on Monday last. It is altogether of a satisfactory character. Additional accommodation is required, and an appeal to the town is about to be made, which we hope will be heartily responded to. The following statistics of the use made of the Science Classes by students, will show the gradually increasing utility of this single side of the Institution:—1857, 578 students; 1862, 717 students; 1866, 1,371 students; 1869, 1,538 students.

WE learn from the *British Medical Journal* that the following courses of lectures will be given at the Royal College of Surgeons during the present year:—1. Six Lectures "On Dermatology," by Prof. Erasmus Wilson, F.R.S., commencing on the 31st inst. 2. Eighteen lectures by Prof. Flower, F.R.S., "On the Anatomy of the Mammalia," commencing February 14th. 3. Six lectures "On the Nature and Treatment of New Growths," by Prof. Birkett. 4. Three lectures "On the Minute Anatomy of the Eye," by Mr. Hulke, F.R.S. Professors Wilson and Flower will lecture on Mondays, Wednesdays, and Fridays, at 4 o'clock. The third and fourth courses will be given in the month of June.

THE following course for the Experimental and Natural Science Gold Medals in Trinity College has been agreed on for 1870. Physics: Jamin, Cours de Physique; Lloyd, Elementary Treatise on the Wave-Theory of Light. Chemistry: Regnault, Cours de Chimie; Naquet, Principles of Chemistry, Second Edition by Cortis; Fresenius, Chemical Analysis, Fourth Edition. Mineralogy and Geology: Dana, System of Mineralogy; Rose, Elements de Crystallographie, Edit. par Regnault; Dana, Manual of Geology, Parts I. II. and IV. Botany, Zoology and Palæontology: Henfrey, Elementary Course of Botany, Parts I. and III.; Lindley, Descriptive Botany, 1858; Bentham, British Flora; Haughton, Three Kingdoms of Nature, Part III.; Greene, Manual of Protozoa and of Cœlenterata; Huxley, Lessons in Elementary Physiology; Dana, Manual of Geology, Part III.

THE Erasmus Smith Professorship of Natural and Experimental Philosophy in Trinity College, Dublin, is now vacant. The second half of the examination for candidates will be held on the 21st. The examiners are the Provost (Dr. Lloyd) and Professors Apjohn, Galbraith, and Jellett. The emoluments of the office are, to a Fellow, if elected, about 600*l.* a year; to the Professor not being a Fellow, 200*l.* a year.

THE Horticultural Society of Cologne is about to extend its original scheme so as to include a school for the scientific teaching of horticulture. It is stated that a range of buildings, to include halls, lecture-rooms, chemical laboratory, dwelling-rooms, &c., is to be immediately erected; and that the society intends to enlarge or rebuild the present orangeries, conservatories, and forcing-houses.

THE *Pall Mall Gazette* of Monday last reports at great length a lecture "On the Forefathers and Forerunners of the English People," given by Professor Huxley, at a meeting held on the preceding evening, under the auspices of the National Sunday League. The lecturer, referring to the arguments now commonly brought forward, upon the assumption that the Irish and English nations belong essentially to different races, denied that there was sufficient proof of the existence of any difference whatever between Celt and Anglo-Saxon, except that of language. He thinks it probable, moreover, that Ireland as a whole contains less Teutonic blood than the eastern half of England, and more than the western half. Our readers may remember that the question of the amount of the Celtic element in the existing English nation was prominently brought before the public in a recent Chancery suit. The claims to originality put forward by the plaintiff in that suit are now disputed by Dr. Daniel Wilson, of Toronto, who communicates to the last number of the *Canadian Journal* a somewhat verbose article pointing out that the results obtained by the plaintiff from craniological investigations were anticipated in all essential particulars in earlier writings of Dr. Wilson's.

THE pressure on our space is so great that we have been unable to lay before our readers the communications on the Suez Canal, presented to the Royal Society by Mr. Bateman, and to the Geographical Society by Lord Houghton; they have, however, been given at some length in the daily press. One point of great scientific interest came out in the discussion at the Geographical Society. Mr. Fowler stated that the evaporation from the Bitter Lakes would require a supply of 250,000,000 cubic feet daily, *i.e.*, a flow in the Canal of $1\frac{1}{2}$ miles per hour. On all hands the Canal is acknowledged to be a complete success, and its probable influence on the trade of Mediterranean ports may be estimated from the fact mentioned by Lord Houghton, that the Emperor of Austria said that "he was there to represent Trieste."

WE are glad to learn from the *Architect* that it has been decided to establish a School of Science and Art at Dover.

THE Swiss are about to supplement, or supersede, their great "Dufour" Map, by another upon a much larger scale. The "Dufour" Map, on a scale of $\frac{1}{100000}$ (about $\frac{5}{8}$ of an inch to a mile), is in twenty-five sheets, and is printed in black only; but the new map is to be on a scale of $\frac{1}{25000}$ for the plains, and $\frac{1}{50000}$ for the mountainous districts. It is to be printed in three colours, and will contain no less than 540 sheets. Roads, towns, and trees are inserted in black, and rivers and glaciers in blue: the third printing, in red, is devoted to contour lines. The distance between each contour line expresses a height of 100 Swiss feet in the mountains, and 33·3 Swiss feet in the plains. It was intended at first to have a fourth printing, in green, for the forests, but this has been abandoned on account of the expense. Several sheets of this map, all admirably executed, have already been issued. At the same time they are reducing the "Dufour" Map to the scale of $\frac{1}{250000}$. This reduction will be in four sheets, and for tourists or for general use will be much more handy than the larger map. It is said that it will be even superior to the original map in the picturesque relief, for which the latter is so remarkable. Three years more will be required to finish the reduced map, of which two sheets are already published.

M. BOUIS has been appointed Professor of Toxicology at the Upper School of Pharmacy in Paris.

WE cull the following notes from the last number of the *Journal of the Society of Arts*:—

The Royal Agricultural Society has been giving its attention to the adulteration of manures and feeding cakes, and is conducting some analyses.

The oxy-hydrogen light is now largely used in Paris for illuminated advertisements and theatrical purposes. Carts with metal reservoirs containing the compressed oxygen for the supply of customers may be seen in the streets. At the Gaieté Theatre, which is one of the largest consumers, cylinders of magnesia or zirconia take the place of the lime cylinders ordinarily used for this light.

In connection with the systematic destruction of timber in Australia, it is mentioned that in the Ballarat district this destruction has been accompanied by a corresponding diminution in the rainfall, and that since 1863 there has been a more or less regular reduction from 37·27in. in 1863 to 14·23in. in 1868. The Government has recently appointed an Inspector of State Forests, whose duty it will be to prevent the waste of timber, and establish nurseries of forest trees in various parts of the colony.

THE BESSEMER PROCESS UNDER PRESSURE

MR. BESSEMER has lately patented a method of conducting his process of converting cast-iron into steel *under pressure*, in order to raise the temperature of the metal during the process of conversion, and to obviate the inconvenience experienced when certain of the purer qualities of Swedish pig-iron made with charcoal, and also some of the less grey and the white hematite pig-irons of this country, when treated by the ordinary process, do not produce sufficient heat in the converting vessel to allow all the steel made from them to retain complete fluidity until it is poured into moulds.

The following description of the apparatus is extracted from *Engineering*, to the editor of which journal we are indebted for the use of the woodcuts.

In the annexed engravings, Fig. 1 is a vertical section of a Bessemer converter constructed on this plan, *a* being the upper part of the converting vessel; *a* ×, the lining of ganister; and *q*, the strong riveted iron shell or vessel on the inside of the mouth of which the iron hoop, *c*, is riveted; while *d* is a flanged iron ring bevelled on the inside, and secured by screwed studs or cotter bolts to the hoop, *c*. A moulded ring, *e*, of fire-brick or other suitable refractory material, forms the escape opening or mouth of the vessel; it is retained in place by means of the flanged ring, *d*.

The aperture in the movable mouth of the vessel thus formed may in some cases be made small enough to retain the gaseous products resulting from the combustion of the carbon or other matter contained in the pig-iron under a pressure much above that of the surrounding atmosphere, so that the combustion going on in the converting vessel may be under "high pressure," and by reason of the combustion so taking place under a pressure much greater than that of the external atmosphere a more intense heat would be produced and imparted to the metal. As a guide to the workmen, Mr. Bessemer states that for the conversion of the purer kinds of Swedish charcoal pig-iron and for mottled or white hematite pig-iron mixed with grey a back pressure in the vessel from 8 to 15 lb. on the square inch will give good results, and in but few cases will a pressure of 20lb. per square inch be necessary. It will be understood that the pressure of the blast of air forced into the converting vessel must be increased in proportion to the back pressure caused by the penning up of the gases within the vessel.

Another arrangement is illustrated in Fig. 2, which represents a vertical section of the upper portion of a converting vessel or chamber in which molten pig or other carburet of iron is to be treated either by the injection of the fluid nitrate into the molten metal, as patented by Mr. Bessemer in March last, or in which vessel the nitrates or other oxygen-yielding salts or substances are so brought in contact with the hot metal as to be decomposed. The outer shell, *h*, of the vessel or chamber is made of thick plates of iron or steel securely riveted and caulked at all joints, and capable of withstanding safely a pressure of from five to ten or more atmospheres. For the convenience of lining the vessel, the upper part may be removed by unbolting the stout flanges, h^1, and one or more hoops, h^2, are riveted to the exterior of the vessel to strengthen it. A lining of fire-brick, ganister, or other refractory material, *i*, is used to defend the outer shell from the high temperature generated within; and previous to its use for conversion, Mr. Bessemer prefers to make a fire in the interior, so as to highly heat the lining and lessen its power of absorbing heat from the metal.

FIG. 1.

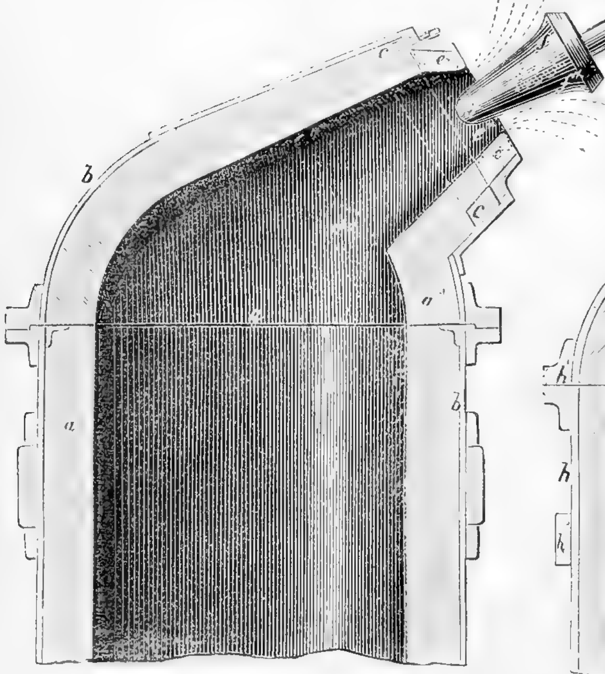

FIG. 2

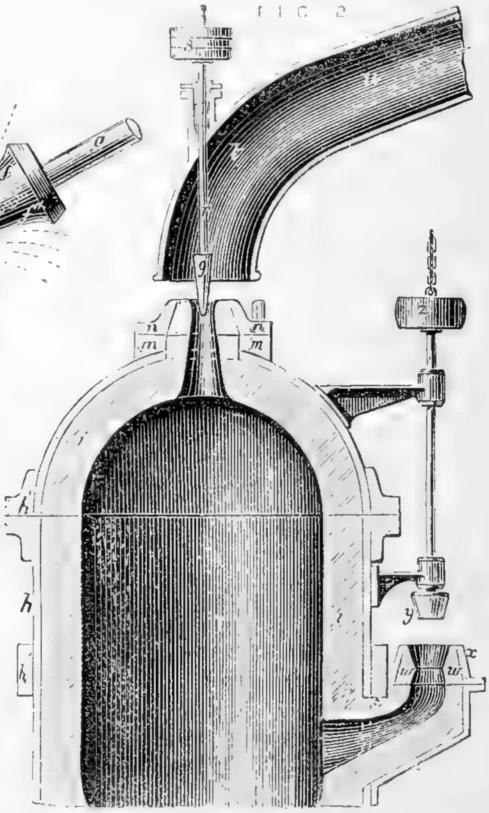

On the upper part of the dome an iron ring, *m*, is riveted, to which a flanged ring, *n*, is fitted. The inside of this ring is conical, and is made to embrace the conical fire-clay ring, *p*, through which the gaseous matters evolved during the process are allowed to escape. A cone of fire-clay or of iron, *g*, is attached to the guide rod *r*, for the purpose of closing or diminishing the area of the outlet opening in the fire-clay ring *p*, and on the upper end of the rod *r* are placed weights, *s*, to regulate the pressure. The rod *r* is guided vertically upward and downward by passing through the tubular guides and stuffing-box formed at *t t*, on the curved exit passage *u*, which leads to a chimney and conveys away the gaseous products escaping from the converting chamber. On one side of the vessel or chamber is a projection, *v*, on the upper part of which a ring of fire-brick, *w*, is retained in place by a conical flanged iron ring, *x*. The opening in the ring *w* serves for the admission of the molten metal to the vessel, after which the cone *y* smeared with fire-clay is lowered down into the opening of the moulded fire-brick *w*, and by means of the weight *z* is retained in place and prevents the escape of gaseous matters during the converting process.

The cone, *y*, and its rod and weight, *z*, are suspended by a chain in the position shown during the period of running in the metal. When the metal so run in comes in contact with the nitrate or other oxygen-yielding materials, large volumes of gaseous matters are evolved, these matters instead of escaping freely from the converter rapidly accumulating in the vessel until the pressure within it is sufficient to raise the cone *g*, and escape by the small annular opening thus made, the pressure being regulated by the weight *s*. Hence the combustion of the carbon contained in the molten iron by reason of its union with oxygen derived from the decomposition of the nitrates or other oxygen-yielding materials will be effected under considerable pressure; and the gaseous products, instead of expanding freely as under the ordinary conditions of combustion, will be in a highly condensed state, by which means their temperature will be considerably raised, and the intense heat so generated will be imparted to the metal and cause it to retain its fluidity.

It will be extremely interesting to watch the working of this new process.

BOTANY

[We have been favoured by the Count Marshal of Austria with the following abstracts of Botanical papers read at the Innspruck Congress.]

Prof. Hildebrand on the Impregnation of Plants

PLANTS intermediate between *Papaveraceæ* and *Fumariæ* gave the greatest quantity of seeds when impregnated with the pollen of another individual of the same species, less when the pollen was taken from another flower of the same individual, and least when the impregnation took place within the flower itself. For *Eschscholtzia Californica*, the proportion of seeds in these three cases was as 24 to 9 to 6. Professor Fenzl says that he obtained abundance of seeds from two species of *Abutilon* by fecundation with pollen from other individuals, and that these operations are best performed between 8 and 9 A.M.

Prof. Fenzl on the Genus Lupinus

SEEDS are with difficulty obtained from plants of this genus in the gardens of Vienna, probably on account of the unfavourable condition of the soil. The species of this genus are still very far from being duly determined, and two-thirds of them, at least, may be eliminated. Professor Koch observes, that the greatest amount of seeds is to be obtained in sandy soil, and that the great number of hybrids are merely varieties in form; the different colours of blossoms being a result of external agents, in the same way as *Nymphæa* gives us lengthened leaves when impregnated with the pollen of *Magnolia*.

Bail on Androgynous Inflorescence

SUCH inflorescences have been found on *Zea*, *Populus*, *Fagus*, *Carpinus*, *Betula humilis* and *Betula alba*, as also on *Pinus nigra*, the small scale, considered as a part of the female blossom, developing itself into an anther.

Prof. Koch on Transformations of Parts of Flowers

IN a fruit of *Solanum melongena*, the five anthers have been transformed into five smaller capsules. A capsule of poppy offers, in the centre of its cavity, a small elevation (the continuation of the axis), bearing a number of smaller capsules.

Prof. Bail on Parasitic Fungi on Insects

Empusa, attacking especially the larvæ of the Fir-Moth, invades also those of *Bombyx Caja*, which were found, sitting on branches of oaks, birches, and firs, killed by this parasite. Larvæ of *Cossus ligniperda*, of all sizes, all thickly covered with the white mucor issuing from their bodies, were found beneath the bark of a completely dried-up birch. These larvæ being kept in moist pots, *Penicillium glaucum* broke out first from their bodies, and was soon superseded by *Isariæ*, the larvæ being covered with moist moss. Those of *Melolontha majalis* are, as well as the perfect insect, destroyed by fungi. The destructive action of the fungi has, however, been exaggerated by the periodical press. Of more than 4,000 larvæ from about ten forest-districts of Prussia and Pomerania, scarcely 29 to 30 per cent. have been destroyed by fungi. The chief morbific fungi were *Isaria farinosa*, identical in all details of structure with *Penicillium*, and *Cordiceps militaris*. The *Melanospora parasitica* Tulasne, found (1858) on all specimens of *Isaria* in the environs of Meran, and on those which had come to their full development, is considered by Dr. Bail to be the higher form of fructification of *Botrytis Bassiana*. *Cordiceps militaris*, with thick, carneous, orange-yellow fructiferous clubs, differs altogether from *Isaria*.

Prof. Koch on the Formation of the Germen

THIS is not, as generally supposed, a concretion of so-called "Fruit-leaves." The germen is part of an axis, supporting the parts of a flower; it may be longer or shorter, as these parts are more or less distant from each other. The apex of the receptacle, or of the axis in general, may become suddenly stationary, and be wrapped up in plastic cellular tissue, a cavity open above, including the ovules (inferior germen), being thus formed; or this cavity includes the germina, either non-connate with the inner wall (*Rosa*, *Calycanthus*, *etc.*), or connate with it (*Cotoneaster*, many *Leptosperms*), or mutually connate, as in the Pomaceous fruits. Such a fruit-receptacle not infrequently includes whole blossoms (*Ficus*). The development of the genuine apex proceeds in two ways. Either the formation of cellules proceeds from the apex itself (as generally in inferior germens), and then its basis is the newest and the apex the oldest portion; or the new formations proceed from the margin of the wall, enlarging upwards, the increase ending in the uppermost portion, as in the fig. Professor Schuler observes, that this takes place only in figs ripened in the second half of the year, whenever the refrigerating action of the north wind has retarded their growth. Professor Koch replies, that the same increase of the margin is observable in the fruit of the *Leguminosæ*. Probably the germina of *Papayaceæ*, *Passifloreæ*, *Capparideæ*, and genuine *Liliaceæ*, likewise take their origin from the axis. The abnormal growth often observed on roses, a sudden prolongation of the axis through the cavity of the fruit-bearing blossoms (sometimes 3 above each other) and leaves, proves the new formations to proceed from the included centre of the extreme apex.

Prof. Martins on the Flora of Southern France

MANY genera of the miocene and pliocene deposits of this and other countries are represented in the living flora of South France. Such are *Laurus nobilis*, L. (= *Laura canariensis*), *Ficus carica*, *Punica granatum*, *Pinus Aleppensis* (found fossil in Unalaska), *Cercis siliquastrum* (near Aix), and *Nerium oleander*, in some localities near Toulon and Nice. All these species have lived through the glacial period; they exist now, however, only on the banks of rivers and rivulets, in localities protected against cold. It must be observed that severe cold is not the necessary consequence of extensive glaciers. A decidedly Indian form, not yet found fossil, is *Anagyris fœtida* (*Piptanthus Nepalensis*, Don.), which brings forth its leaves in October, and its blossoms in January and February. Other extraneous forms are: *Myrtus communis* (represented in Peru by *Myrtus myricoides*), *Chamærops humilis* (near Villefranche and Toulon, represented in the Caroline Islands by *Cham. serrulata*, Pursh, and *Cham. hystrix*), and *Ceratonia siliqua*, whose native country is still doubtful. *Cham. humilis* is now extirpated by the avidity of collecting botanists. Professor Koch says that *Anagyris fœtida* belongs rather to the Cytiseæ, or Genisteæ, than to any exotic family, and doubts *Ceratonia silliqua* being a leguminose. Professor Martins replies that he thinks *Anag. fœtida* to be closely related to *Thermopsis*, and observes that about 200 Lapland species occur in South France; that the littoral plants are partly the same as those on the coasts of the Atlantic, except *Spartina versicolor*, an exclusively American form, and hints at the importance of the study of fossil plants for the thorough knowledge of those existing in the present period.

Prof. Hildebrand on Marsilia

SPECIMENS of this plant, growing beneath the surface of water, regularly produce leaves which spread over its surface, and follow its level, while, if kept dry, they never produce such leaves. The leaves grown in air have stomata on both their surfaces; those grown in water have stomata only on their upper surface. Dr. Reichardt observes, that wild specimens of *Marsilia* have constantly been found provided only with large floating leaves. Professor Hoffmann says, that abundant fruits are obtained from *Marsilia* by cultivating it in slimy soil. Professor Hildebrand remarks, that specimens grown in water, and not bearing fruit, propagate themselves with astonishing rapidity without any fecundation.

SCIENTIFIC SERIALS

THE January number (N.S., No. 37) of the *Quarterly Journal of Microscopical Science* opens with an article entitled "Notes on Sponges," by Prof. E. Perceval Wright. In this the author indicates some peculiarities of the structure of the sponge-body of *Hyalonema mirabilis*, and describes two new species of deep-sea sponges, namely *Aphrocallistes Bocagei*, which is exquisitely figured by Mr. Ford, and the type of a new genus which the author names *Wyvillethomsonia Wallichii*. We cannot help protesting against this new generic name, as being barbarous in the highest degree. Mr. William Archer, of Dublin, continues his valuable descriptions of new or imperfectly-known fresh-water Rhizöpoda, and Mr. W. S. Kent describes and figures a curious new form of Polyzoön, from the Victoria Docks, where the animal lives attached to the surface of specimens of the *Cordylophora lacustris*. For this Polyzoön, which the author regards as the type of a new family (*Homodiœtidæ*) of the Ctenostomata, he proposes the name of *Victorella pavida*. A singular crustacean parasite found on *Nereis cultrifera* is described and figured by Dr. W. C. McIntosh. Besides these, we have a paper on the distribution of nerves to the vessels of the connective tissue in the hilus of the pig's kidney, and on the ganglia connected with these nerves, by Dr. James Tyson, of Philadelphia; an abstract of a dissertation on the minute structure of the human umbilical cord, by Dr. Köster; a translation of Dr. E. Van Beneden's description of his *Gregarina gigantea* (with a plate); and an abstract of an important memoir, by Dr. Kowalewsky, on the relationship of Ascidians and Vertebrates. The only original article on the microscope itself is one by Dr. G. W. Royston-Pigott, on certain imperfections and tests of object-glasses. This number also contains a review of Mr. Hincks's "History of British Hydroid Zoophytes."

IN the *Geological Magazine* for the present month (No. 67), the most important paper is the first part of a memoir on the sequence of the Glacial Beds, by Mr. Searles V. Wood, jun., in which the author indicates his views as to the best classification to be adopted in the treatment of these difficult deposits, and discusses the characters of the beds and evidence attainable as to the sequence of the phenomena attending their deposition. Mr. David Forbes publishes some remarks on the contraction of igneous rocks in cooling, in which he again maintains, chiefly from his own experiments, that the amount of this contraction is much less than is generally believed, on the authority of Bischof. His paper is really a vindication of himself from some remarks in a memoir by the Rev. O. Fisher. Mr. John Rofe describes some peculiar perforations observed in the lower surfaces of slabs of mountain limestone, at considerable elevations, in various localities, which have already been noticed by several writers, and ascribed by some to lithodomous marine mollusca. Mr. Rofe regards them as produced by snails, either by the rasping action of their odontophores alone, or by this aided by an acid salivary fluid. Mr. Ruskin continues his notices of banded and brecciated concretions. Mr. J. Clifton Ward remarks upon the denudation of the lake-district, which he ascribes chiefly to subaërial action. In a paper on the formation of the Chesil Bank, Mr. T. Codrington maintains, in opposition to Messrs. Bristow and Whitaker, that the streams coming from the land have had nothing to do with the production of this bank, or the excavation of the channel by which it is separated from the mainland. He ascribes the formation of this and similar banks solely "to the heaping-up action of waves breaking when they reach a depth of water about equal to their own height."

THE *Revue des Cours Scientifiques* for the 8th inst. contains a lecture, by Prof. Lorain, on the application of the graphic method to the clinical study of disease. Translations are likewise given of Prof. Helmholtz's address to the meeting of German Naturalists and Physicians at Innspruck, and of Mr. Geikie's account of the same meeting, published in the first number of NATURE.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 16, 1869.—The following were among the papers read:—"On the Thermodynamic Theory of Waves of Finite Longitudinal Disturbance," by Prof. Rankine, F.R.S.; "On Approach caused by Vibration," by Prof. Guthrie. The author observes that when a vibrating tuning-fork is held near to a piece of cardboard, the latter has a tendency to approach the fork. Starting from this experiment, a series of experiments is described, having for their object the determination of the cause and conditions of the fundamental observed fact. It is shown that no sensible permanent air-currents, having their source at the fork's surface, are established; and hence that the approach of the card to the fork is not due to the expansion of such currents, as in M. Clement's experiment. The modifications are examined which Mr. Faraday's surface-whirlwinds on a vibrating tuning-fork undergo when the fork vibrates in the neighbourhood of a sensibly rigid plane. It is shown that a delicately-suspended card approaches the fork when either of the three essential faces of the fork is presented to the card, and that the approach takes place from distances far exceeding the range of Mr. Faraday's air-current. That the action between the card and fork is mutual, is shown by suspending the latter. Also one vibrating fork tends to approach another in whatever sense their planes of vibration may be towards one another. The mean tension of the air surrounding a vibrating fork is examined by enclosing one limb of the fork in a glass tube. It appears that the vibrating fork displaces air. The question whether the equilibrium between two equal and opposite forces acting on a body is disturbed by submitting one of the forces to successive rapid, equal, and opposite alterations in quantity, is answered in the negative by an experiment which shows that the equilibrium of a Cartesian diver is not disturbed by submitting the water in which it floats to vibration. Various modifications are introduced into the nature of the surface which receives the vibrations, such as making it a narrow cylinder with one end closed, making it of cotton-wool, &c. It is found that in all cases the suspended body approaches the vibrating one. The author concludes that the effect of apparent attraction is due to atmospheric pressure, and that this pressure is due to undulatory dispersion. It is suggested that the dispersion of the vibrations which constitute radiant heat may cause bodies to approach, being pushed, not dulled.—"On Abstract Geometry," by Prof. Cayley. "I submit to the society the present exposition of some of the elementary principles of an abstract m-dimensional geometry. The science presents itself in two ways: as a legitimate extension of the ordinary two-and three-dimensional geometries; and as a need in these geometries and in analysis generally. In fact, whenever we are concerned with quantities connected together in any manner, and which are, or are considered as, variable or determinable, then the nature of the relation between the quantities is frequently rendered more intelligible by regarding them (if only two or three in number) as the co-ordinates of a point in a plane or in space; for more than three quantities there is, from the greater complexity of the case, the greater need of such a representation; but this can only be obtained by means of the notion of a space of the proper dimensionality; and to use such representation, we require the geometry of such space. An important instance in plane geometry has actually presented itself in the question of the determination of the curves which satisfy given conditions; the conditions imply relations between the co-efficients in the equation of the curve; and for the better understanding of these relations it was expedient to consider the coefficients as the co-ordinates of a point in a space of the proper dimensionality. A fundamental notion in the general theory presents itself, slightly in plane geometry, but already very prominently in solid geometry; viz., we have here the difficulty as to the form of the equations of a curve in space, or (to speak more accurately) as to the expression by means of equations of the twofold relation between the co-ordinates of a point of such curve. The notion in question is that of a k-fold relation,—as distinguished from any system of equations (or onefold relations) serving for the expression of it,—and giving rise to the problem how to express such relation by means of a system of equations (or onefold relations). Applying to the case of solid geometry my conclusion in the general theory, it may be mentioned that I regard the twofold relation of a curve in space as being completely and precisely expressed by means of a system of equations ($P=0$, $Q=0$, . . $T=0$), when no one of the functions, P Q, . . . T as a linear function, with constant or variable *integral* coefficients, of the others of them; and when *every surface whatever* which passes through the curve has its equation expressible in the form $U=AP+BQ$ . . . $+KT$, with constant or variable integral coefficients, $A+B$ . . . K. It is hardly necessary to remark that all the functions and coefficients are taken to be rational functions of the co-ordinates, and that the word integral has reference to the co-ordinates."

January 6.—"Some account of the Suez Canal in a letter addressed to the president," by J. F. Bateman, F.R.S.

Entomological Society of London, January 3.—Mr. H. W. Bates, president, in the chair. The fifth part of the "Transactions for 1869" was on the table. A splendid collection of butterflies was sent for exhibition by Mr. Hewitson; it included 135 new species, and many other rarities, the whole having been captured by Mr. Buckley in South America. Observations thereon were made by Mr. Buckley, the President, Mr. Higgins, and Mr. Wallace.—Professor Westwood, Mr. Bond, Mr. Pascoe, Mr. Albert Müller, and Mr. Quaritch, also exhibited various objects, and made remarks thereon.—Papers were read on *Ephemeridæ*, by the Rev. A. E. Eaton; on *Callidryas*, by Mr. A. G. Butler; on *Catasarcus*, by Mr. F. P. Pascoe; and on the genera of *Coleoptera*, studied chronologically (Part I., from 1735 to 1801), by Mr. G. R. Crotch.

Royal Horticultural Society, December 21, 1869.—*Scientific Committee*.—Mr. W. W. Saunders in the chair. The secretary, Rev. M. J. Berkeley, exhibited a leaf of Aerides "Foxbrush" with a peculiar form of spot, differing from any he had previously seen.—Mr. Laxton sent specimens of peas of the most varied character, the result of a single cross.—A very interesting paper "On the Fertilisation of Grasses," from Dr. R. Spruce, from which the following are extracts, was communicated through Dr. Masters. The paper had reference to the statement of M. Bidard that grasses are usually self-fertilised while in the bud: it will be published *in extenso* in the Journal of the Society:—

"In gently-flowing rivers of tropical America grow many fine aquatic grasses, species of *Luziola*, *Oryza*, *Leersia*, &c. The following note is from my journal, under date December 1849, when threading in my canoe among the islands of the Trombetas:—'This channel was lined on both sides by a beautiful grass—a species of *Luziola*—growing in deep water, and standing out of it two or three feet. The large male flowers, of the most delicate pink, streaked with deep purple, and with six long yellow stamens hanging out of them, were disposed in a lax terminal panicle; while the slender green female flowers grew on the bristle-like branches of much smaller panicles springing from the inflated sheaths of the leaves that clothed the stem. As the Indians disturbed the grassy fringe with the movement of their paddles, the pollen fell from the anthers in showers,' and would, doubtless, some of it, attain the female flowers disposed for its reception. A parallel case to the above is that of the common maize (*Zea Mays*, L.), where the male flowers are borne in a long terminal raceme or panicle, and the female flowers are densely packed on spikes springing from the leaf-axels.. Here the male flowers must plainly expand before the pollen contained in their anthers can be shed on the female organs below, whether of the same or of a different plant. That there are frequent cross-marriages in maize is evidenced by the numerous varieties in cultivation in countries where it is a staple article of food, as in the Andes of Ecuador, where nine kinds, varying in the colour of the grain (through white, yellow, and brown, to black), in its size, consistence, and flavour, are commonly cultivated; besides many others less generally known. In *Phærus scaber* (H. B. K.) another tall broad-leaved grass, the spikelets stand by twos on the spike—a sessile female spikelet, and a stalked male spikelet. In the same forest grasses of the genus *Olyra*, whereof some species, such as *O. micrantha* (H. B. K.), rise to 10 feet high, and have lanceolate leaves above 3 inches broad, and a large terminal panicle, with capillary branches, like those of our *Aria cæspatosa*: it is the lower flowers that are male, with large innate (not versatile) anthers, and the upper that are female, with two large stigmas, that are either dichotomously divided, or clad with branched hairs, thus exposing a wider surface to the access of the pollen. And as the panicle is often pendulous, many of the male flowers, although placed lower down the axis, are actually suspended over the terminal female flowers. It is generally to be remarked of diclinous grasses, that either the male flowers are very numerous, as in *Zea Mays*, or the stamens are multiplied in each male flower, as in *Pariana*, *Leersia*, *Guadua*, &c.; or the stigmatic apparatus of the female flowers is enlarged, so as almost to insure impregnation, as in *Olyra* and *Tripsacum*. In the *Bambuseæ* I have gathered belonging to the genera *Guadua*, *Merostachys*, and *Chusquea*, the flowers are more or less polygamous, and the stamens of the male flowers often doubled. But there is scarcely a genus in the whole order which is not described as having some flowers by abortion, neuter or male, and especially those that have biflorous spikelets, such as the *Paniceæ*. Some grasses, of normally hermaphrodite genera, are not unfrequently truly unisexual, such as certain species of *Andropogon*. I have occasionally seen panicles of *Orthocladus rariflorus* (Nees), a grass peculiar to the Amazon, quite destitute of stamens, and therefore purely female. To come home to our own country: is all the pollen wasted that a touch or a breath sets free from the flowers of grasses in such abundance? Watch a field of wheat in bloom, the heads swayed by the wind, lovingly kissing each other, and doubtless stealing and giving pollen. Consider, too, that throughout Nature, heat or moisture, or both, are essential to the emanation of the impregnating influence. In all our *Festuceæ*, as well as in *Cynodon*, *Leersia*, and some other genera, the stigmas are protruded from the side or from the base of the flower at an early stage, often before the stamens of the same flower are mature—thus as it were inviting cross-fertilisation from the more precocious stamens of other plants which are already shedding their pollen. All who have gathered grasses will have remarked that some have yellow anthers, others pink or violet anthers; and that anthers of both types of colours may co-exist on distinct individuals of the same species. The same peculiarity is just as noticeable in tropical grasses, and (without professing to give a complete physiological explanation of it) this is what I have observed respecting it. The walls of the anther-cells are usually of some shade of purple, but are so very thin and pellucid, that when distended with mature pollen the yellow colour of the latter is alone visible. When the pollen is discharged, the anthers resume their original purple colour, shortly, however, to take on the pallor or dinginess of decay. Where the anthers emerge of a purple hue, and change from that to brown, it will probably be found that they have discharged their pollen while still included in the flower. These observations, made without any reference to the question now in hand, require to be renewed and tested; and in them, as in all that precedes, I am open to correction. Of grasses with bisexual flowers, there are two ways in which the ovary may be fertilised, viz., either by the pollen of its own flower (closed or open), or by that of other flowers, after the manner of the diclinous species. In the latter case, the pollen may be transported by the wind, or in the fur of animals (as I have observed the seeds of *Selaginellas* in South America), or in the plumage of birds. The agency of insects has not been traced in the fertilisation of grasses, but may exist. The little flies I have seen on the flowers of grasses seemed bent on depositing their eggs in the nascent ovaries, but may also have aided in cross-fertilisation. In the Amazon Valley grasses are often infested by ants, who, indeed, leave nothing organic unvisited throughout that vast region; and they also, I think, cannot help occasionally transferring grains of pollen from one flower to another. The flowers of palms and grasses agree in being usually small and obscurely coloured, but contrast greatly in the former being in many cases exquisitely and strongly scented, whereas in the latter they are usually quite scentless. The odour of palm-flowers often resembles that of mignonette; but I think a whole acre of that 'darling' weed would not emit more perfume than a single plant of the fan palm of the Rio Negro (*Mauritia Carara*, Wallace). In approaching one of these plants through the thick forest, the sense of hearing would perhaps give the first notice of its proximity, from the merry hum of winged insects which its scented flowers had drawn together, to feast on the honey, and to transport the pollen of the male to the female plants; for it is chiefly diœcious species of palms that have such sweet flowers. The absence of odoriferous flowers from the grasses seems to show that insect aid is not needed for effecting their fecundation, but does not render its accidental concurrence a whit less unlikely. That grasses, notwithstanding their almost mathematical character, vary much as other plants do, is plain from the multitude of osculating forms (in such genera as *Eragrostis*, *Panicum*, and *Paspalum*), which puzzle the botanist to decide when to combine and when to separate, in order to obtain what are called 'good species.' Hence the conclusion is unavoidable that in grasses, as in other plants, variations of surrounding conditions induce corresponding modifications of structure, and that amongst the former must be enumerated cross marriages, however brought about. If the flowers of grasses be sometimes fertilised in the bud, it is probably exceptional, like the similar cases recorded of orchids and many other families. To conclude: the more I ponder over existing evidence, the more I feel convinced that in its perfect state every being has the sexes practically separated, and that natural selection is ever tending to make this separation more complete and permanent; so that the hypothesis of Plato, that the prototype even of man was hermaphrodite, may one day be proved to be a fact!"

—Mr. Saunders alluded to the circumstance that the dead bodies of a species of fly might occasionally be found imprisoned in the flowers of *Lolium perenne*, as if the plant exerted some poisonous influence on the insect. Mr. A. W. Bennett stated, as a result of his observations, that it is impossible to predicate of any given family, whether its members are self or cross-fertilised. In the same group some species may be cross-fertilised, others self-fertilised. Many winter-flowering plants are self-fertilised, and amongst them the common *Poa annua*. Mr. Horne stated that in India different varieties of maize remain constant, even though grown in adjacent fields, so that it would seem as if no crossing took place in this instance.—A conversation then ensued as to the best method of conducting in future the meteorological observations at Chiswick, when Mr. Glaisher stated that he would be willing to reorganise the system of observation in such a manner as to introduce the requisite changes, without impairing the value of the record kept at Chiswick for upwards of forty years. In reference to ground temperature, he stated that at a depth of twenty-five feet the ground was coldest in July, and warmest in January.

Institution of Civil Engineers, December 21.—Annual General Meeting. Charles Hutton Gregory, Esq., president, in the chair. Referring to the business at the ordinary general meetings, of which there were twenty-two during the past session, attention had been directed by the papers read, and by the discussions upon them, to the use of machinery in lieu of gunpowder for "getting" coal; to cylinder foundations for bridges and other similar structures; to the Midland line of the Mauritius railways, where exceptionally steep gradients and sharp curves were necessarily adopted; to some of the chief peculiarities of American locomotives and rolling stock; to works carried out in connection with the river Witham and estuary, for the drainage of the fens and the improvement of the outfall of the navigation; to the past and present condition of the outfall of the river Humber, and of its peculiar feature, Spurn Point; to the New Ferry and the New Brighton piers and landing-stages on the river Mersey; to the Low-water Basin at Birkenhead, and the extensive sluicing operations for maintaining the basin at its proper depth; to the lagoons and marshes on certain parts of the shores of the Mediterranean; to the mechanical details of construction of lighthouse apparatus and lanterns; to the Roman Rock lighthouse, Cape of Good Hope; to the standards of comparison for testing the illuminating power of coal-gas; and lastly, to an able summary, by a foreign engineer, of the present state of knowledge as to the theory of the strength and resistance of materials of construction. The originality, labour, and ingenuity displayed in these communications, had led to the award of Telford Medals and Premiums of Books to Messrs. Jules Gaudard, W. Shelford, T. N. Kirkham, J. Ellacott, and D. T. Ansted, F.R.S.; of a Watt Medal and a Telford Premium of Books to Mr. Z. Colburn; of Telford Premiums of Books to Messrs. W. H. Wheeler, J. R. Mosse, I. Bell, J. Milroy, S. P. Bidder, jun., and C. J. Chubb; and of the Manby Premium of Books to Mr. D. M. Henderson.

In addition to the ordinary general meetings, there were six supplemental meetings, for the reading and discussion of papers by the students. For the papers read at these supplemental meetings, Miller Prizes had been awarded to the following students: Messrs. E. Bazalgette, F. H. Mort, T. J. Ellis, T. R. Gainsford, C. H. G. Jenkinson, and G. H. Roberts.

After a statement of the financial condition of the institution, it was announced that the council had recently taken vigorous measures to vindicate the honour of the profession, which had been unjustifiably assailed by the Government of India, in a notification, the plain intention of which could only be to charge civil engineers with recognising as legitimate the receipt of commissions from others than their immediate employers, and in addition to their salaries, where so remunerated. The Secretary of State for India had put on record "that he regards with implicit confidence the indignant repudiation by the institution of the recognition of any such practice as that referred to," and that he would call upon the Governor-General in Council for an explanation of the circumstances which led to the issue of the objectionable notification. A sufficient time had not yet elapsed for an answer to be received from India to the remonstrance of the institution. In the meantime, the council felt assured that the steps they had taken would meet with cordial approval. In inviting attention to this report, the presentation of which terminated the trust confided to them by the last annual general meeting, the council observed that they had laboured so to direct the affairs entrusted to them, that the discharge of their duties might be attended with advantage to the institution.

The following gentlemen were elected to fill the several offices in the Council for the ensuing year:—Charles Blacker Vignoles, President; Joseph Cubitt, Thomas Elliot Harrison, Thomas Hawksley, and George Willoughby Hemans, Vice-Presidents; James Abernethy, William Henry Barlow, John Frederic Bateman, Joseph William Bazalgette, Nathaniel Beardmore, Frederick Joseph Bramwell, James Brunlees, John Murray, George Robert Stephenson, and Edward Woods, Members; and Edward Middleton Barry and Lieut.-Col. Andrew Clarke, C.B., R.E., Associates.

EDINBURGH

Royal Physical Society, December 22.—Professor Duns, president, in the chair. The following gentlemen were elected members:—Messrs. Gibson and Durham. The office-bearers for the sessions were elected as follows:—Presidents, Professor John Duns, D.D., R. F. Logan, C. W. Peach; Council, E. W. Dallas, T. S. Wright, M.D., James M'Bain, M.D., R.N., R. Brown, Stevenson Macadam, A. Wilson; Secretary, John A. Smith, M.D.; Treasurer, G. Logan, W.S.; Assistant Secretary, J. Boyd Davies; Honorary Librarian, A. Taylor.—Notice of the occurrence of *Gonoplax angulata* off the coast of Mull, by M. Watson, M.D. This rare crab was taken in September last by Dr. Watson, when dredging in "Bloody Bay," on the north coast of Mull, in about twenty-five fathoms water. The dredge was filled with soft mud, along with a great quantity of the *Pennatula* and *Virgaelaria*. As far as he could learn, it was the first time it had been taken on the Scottish coasts. Mr. Bell, in his "Brit. Crustacea," says it is not known to have been taken in Scotland. This species has not been taken on the east coast of Scotland nor in Shetland. Mr. Peach stated it was got on the south coast of England, on the Welsh coast, and also in Ireland. It is a Mediterranean species. The specimen was a young male, and was an interesting addition to the list of Scottish crustacea. Dr. Duns exhibited a fine species of Gurnard (*Trigla*), which had been forwarded to the New College Museum by the Rev. Walter Wood, Elie, to whom it had been brought as a novelty by a fisherman. He pointed out a number of features in which the specimen differs from those described by Yarrell, Fleming, Gunther, and others, but was inclined to regard it as a variety of *Trigla pini* (Block).

DUBLIN

Natural History Society, January 5.—The Rev. Professor Haughton, M.D., F.R.S., in the chair. Mr. W. Andrews read a paper "On the inhabitants of rockpools and caves, Dingle Bay." The rockpools of Dingle Bay had been examined in October 1868, and were teeming with animal life. After reminding the members of the pleasure of being naturalists, Mr. Andrews said that in the present paper he would speak of the Actinozoa that he had met with in Dingle Bay, and among the species that he mentioned the following appear to be of most interes as being apparently unrecorded as Irish:—*Aiptasia couchii; Cerianthus*, a species near *C. Lloydii*, *Stromphia churchiæ*, *Balanophyllia regia*. Living specimens of *Caryophyllia smithii* were dredged in fifty fathoms of water. Mr. Jeffrey's paper "On Deep-sea Dredging" (*Vide* NATURE, p. 135), was referred to, as proving that this coral was a deep-sea species, whereas Mr. Gosse and Professor Wright twelve years ago described it as being a littoral zone species. Great quantities of *Nullipora compressa* were met with, and many beautiful coloured specimens of the egg-cases of *Pyrpura lapillus* with the young shell in them. The author then proceeded to refer to coral-reefs, and stated that he now believed that the *Millepora alcicornis* Linn. was not a coral. It was a true *Eschara*, and took the place in these seas of the *Pœcillopora* of the tropics. At another time he would refer again to the stony corals met with in Dingle Bay, and enter into the full history of their affinities and structure.—Dr. A. Macalister read a paper "On the Mode of Growth of Univalve Shells." Referring to Canon Moseley's memoir on the geometrical forms of turbinated and discoid shells, he stated that he had made a large number of measurements to determine the logarithmic spiral of the different families of Gasteropods, with the hope that the number found to express the ratio of the geometrical progression of the dimensions of their whorls might be of use in classification. In this he had to a certain extent succeeded, as the tables exhibited showed. Mr. Lalor was glad to see the result of Dr. Macalister's work, as it quite corroborated some investigations that he had made on this interesting subject several years ago.—The Rev. Professor Haughton then read a paper "On the Geometrical Characters of Muscles." He alluded to the researches of J. A. Borelli, as given in his "De Motu Animalium," published at Rome in 1680, and stated that the classification of muscles therein mentioned was surprising for its accuracy. Dr. Haughton had modified and added to it as follows:—I. Muscular fibres being on same plane: 1. The fibres parallel; 2. The fibres intersect; 3. The fibres curved (sphincter). II. Muscular fibres being on curved surfaces: 1. Where the fibres formed right lines; 2. Where no line on the surface was a right line.—Mr. Lalor read a paper, not containing any original matter, "On the Anatomy of the Oyster."

MANCHESTER

Literary and Philosophical Society, December 28, 1869.—J. P. Joule, LL.D., F.R.S., &c., president, in the chair. "On Pollen considered as an aid in the Differentiation of Species," by Charles Bailey. The author, having recently examined the pollen of several thousand species of plants, is led to think that the characters presented might prove useful as a means of differentiation in allied species; the following notes are thrown out as indications of some of the more noticeable distinctions to be drawn:—

1. FORM.—It has long been noticed that certain types of pollen are characteristic of the natural order to which the plants which produce them belong, as, for instance, the peculiar pitted polyhedral pollen of the *Caryophyllaceæ*, the spherical spiny pollen of the *Malvaceæ*, the large triangular pollen of the *Onagraceæ*, the peculiar pollen of the *Coniferæ*, or the elliptical pollen of the *Liliaceæ* and other monocotyledonous orders; in fact, most orders possess a type sufficiently marked to be characteristic of each. This statement, however, must be accepted with limitations; the *Compositæ*, for instance, have three or more well-marked types, represented by the beautifully sculptured pollen of the Chicory, the minute oval spiny pollen of the Asters, Calendulas, Cacalias, &c., and another form wholly destitute of spines, as in the *Centaurea Scabiosa*. There are, besides, other natural orders where similar variety occurs. But differences of form are met with in plants of the same genus, by which the one species or the other is readily marked off by its pollen; thus, the pollen grain of *Anemone sulphurea* is roundish, but that of *Anemone montana* is elliptic; the pollen of *Aronicum Doronicum* is much more elongate than that of *A. scorpioides*; and while the grains of *Ranunculus philonotis* are round and yellow, those of *R. platanifolius* are elliptic, white, and smaller.

2. MARKINGS.—The pollen of the *Geraniaceæ* and *Campanulaceæ* is for the most part globular, but while some of the grains are quite smooth, others are covered with spines; thus, the pollen of *Campanula Media* has a number of short spines sparsely scattered over the surface of the grain, but *C. rapunculoides* is wholly destitute of them. In other plants these spines are replaced by tubercles, and both spines and tubercles vary greatly in length and number; for example, in *Valeriana tuberosa* the spines are only half the length of those on the pollen of *V. montana*, the grains being also slightly smaller. The pollen of the *Liliaceæ* is often covered with a more or less prominent reticulation, which is subject to much variation; compare, for example, the coarse network which invests the pollen of *Lilium croceum* with the finer reticulation of *L. canadense*, the grains of the latter species being much more globose and smaller.

3. DIMENSIONS.—Some instances of the differences observable in the size of pollen grains have already been published by Professor Gulliver, whose measurements of the pollen of various species of *Ranunculus* show the help that may be derived from this character; *R. arvensis* is nearly twice the size of *R. hirsutus* their dimensions being respectively $\frac{1}{470}$ and $\frac{1}{888}$ of an inch. For some noticeable differences, compare the smaller pollen of *Epilobium brachycarpum* with the larger pollen of *E. Fleischeri*, or that of *Senecio gallicus* with *S. incanus*, the spines on the latter species being also much coarser. Again, the pollen of *Silene acaulis* is but half the size of that of *S. alpina*, the latter having some beautiful markings in addition; the pollen grains of this genus differ from the usual caryophyllaceous type in not having the pits or depressions common in the order, so that the grains become spherical rather than polyhedral.

4. COLOUR.—This is not so reliable a character for differentiation as the others noticed, since species differ amongst each other according to the soil, &c. The pollen of *Ajuga genevensis* is yellow, but of *A. pyramidalis* is usually white; again, while the grains of *Ornithogalum umbellatum* are large and yellow, those of *O. nutans* are small and white. In regard to the mounting of these objects for the microscope, they show to the best advantage when put up perfectly dry; the cells should be sufficiently shallow to admit of no more than a single layer, and at the same time deep enough to permit the grains to move about. If pollen is mounted soon after it has been discharged from the fresh anthers, the fovilla is apt to condense on the covering glass, and the slide soon becomes useless. The stamens taken from an unopened flower-bud furnish the best and cleanest pollen, and these should be selected in preference to those taken from the fully-developed flower. Canada balsam, glycerine, and other media are occasionally helpful in making out structure; thus the pores of *Campanula rotundifolia*, *Phyteuma Halleri*, and other allied species are made much more distinct when mounted in balsam.

Microscopical and Natural History Section.—December 6, 1869.—J. Watson, Esq., president of the section, in the chair. Mr. W. Boyd Dawkins, M.A., F.R.S., was elected a member of the section. Mr. J. B. Dancer, F.R.A.S., read a short paper on some of the new Hydro-carbon Compounds from which he had obtained very beautiful polarising objects for the microscope.

PARIS

Academy of Sciences, January 3.—M. Coste was elected vice-president, and MM. Chasles and Decaisne members of the general administrative committee. The outgoing president, M. Claude Bernard, gave an account of the present condition of the publications of the Academy, and announced the changes among the members and correspondents during the past year. The following memoirs and communications were then presented: "On the demonstration relative to the sum of the angles of a triangle," by M. Bertrand; "On the nascent state," by M. H. Sainte-Claire Deville; "On the constitution of the solar aureola, and on some peculiarities of Geissler's tubes," by Father Secchi. The publication of Father Secchi's letter is delayed on account of some illustrations which accompanied it not being ready. The memoirs presented to the Academy were as follows:—"On the poinçonnage (piercing) of metals and plastic substances," by M. Tresca; "On a postulate of Euclid," a note by M. Lionnet, and a note on the same subject by M. Fleury. Of the correspondence addressed to the Academy, the more important were a note by M. Tréve on the action of magnetism on gases, a communication by M. Houzeau "On the origin of nitrogen gas in oxygen supposed to be pure," one by M. Gaudin indicating the process employed in the fabrication of artificial precious stones, and one by M. Prillieux on the movements of grains of chlorophyll under the influence of light. Some account of M. Tréve's note, which is of very great interest, will be given subsequently. The other elections are referred to elsewhere.

BERLIN

German Chemical Society, Dec. 27.—The following papers were read:—Ed. Schaer: "On some relations shown by Coppersalts in the presence of Cyanides."—Th. Zincke: "On the Synthesis of Aromatic Acids." (The author treated the ether of monochloroacetic acid with bromide of phenyle and molecular silver thus producing botaylic ether).—Kempf: "On Chlorocarbonate and Carbaminate of Phenyle."—Vogel: "On recognising Sulphuret of Carbon in Gas."

ITALY

Reale Instituto Lombardo di Scienze e Lettere.—"Report of Researches in the Class of Mathematical and Natural Sciences." (Session, 1868-69.) By Professor Schiaparelli.

Mathematics.—In a memoir "On the Equations which determine the points of contrary flexure of Elliptic Curves," Prof. Brioschi gives the methods of determining the points of flexure of those curves of the n'th order which have $\frac{n(n-3)}{2}$ double points or cusps. Prof. Cremona has studied "The Transformation of Hyperelliptic Curves," that is to say, of those curves whose co-ordinates may be expressed rationally by means of a parameter λ, and the square root of an integral function of even order of this same parameter. The "Number of Moduli of the Equations and Algebraic Curves of a given genus" has been investigated by Professors Cremona and Casorati, whose results tend to support the rule given by Riemann for determining the said number, also the different rule proposed for the same purpose by Cayley. A memoir by Prof. Boltrami of Bologna contains "Researches on a new element introduced by Christoffel into the Theory of Surfaces," which is nothing else than the quantity by which it is necessary to multiply the infinitesimal angle between two geodetics proceeding from the same point, in order to obtain the length of the arc of any orthogonal trajectory to the two geodetic lines in question, comprised between the same lines. Prof. Geiser of Zurich has generalised, for any number of dimensions, or translated into an analytical fact for any given number of variables, "A theorem of Steiner relating to properties common to all the Maximum Triangles inscribed in a given Ellipse." A communication from the illustrious Clebsch, professor at Göttingen, refers to those "Surfaces which have the property of being representable point by point above a plane." Such representations are known to afford an extremely powerful instrument of geometric analysis. Prof. Bardelli has collected and demonstrated all the formulæ proposed by various geometers (Euler, Monge, Rodrigues Broschi), for the very useful problem of the "Transformation of Co-ordinates in Space," showing the relation and the geometric significance of the several systems of auxiliary variables adopted by those authors. Finally, amongst the mathematical researches may also be included a note by Schiaparelli on "The principle of the Arithmetic Mean in the calculation of Observations," and one by Prof. Porro, "On the new Cleps-cyclic Theodolite," an instrument invented by the author for rapid surveying.

Hydraulics.—The memoirs presented to the Institute under this head were chiefly of local interest, relating to the rivers and canals of Upper Italy. There is also one by Senator Lombardini, entitled "Geographical and Hydrological Researches in the Regions of the Upper Nile and Central Africa."

Astronomy, Meteorology, and Terrestrial Physics.—In a memoir entitled the "Variations of the Eccentricity of the Earth's Orbit, and of Terrestrial Climates in the Geological Epochs," Schiaparelli endeavours to prove that the changes of eccentricity in the orbit cannot be the cause of the great oscillations of temperature which have taken place in geologic epochs, and that the origin of the glacial periods must be sought elsewhere.—Prof. Cantoni, speaking of "The Rains of the Autumn of 1868 in Upper Italy," discusses the cause of the terrible inundations of that year. Cavalleri communicates an "Observation on the Aurora Borealis of the 13th of March, 1869," which was visible over a large part of Europe; and lastly, Prof. Rialti of Forli communicates a note "On the Cause of the Incandescence of Bolides," which gave occasion to Prof. Cantoni to make a calculation respecting the heat developed in bolides by the resistance of the air, analogous to those which had been made on the same subject by Reichenbach in Germany and Marsh in America.

Physics.—Prof. Cantoni has made a series of researches on "Frictional Electrical Machines," and especially that of Holtz; the "Theory of the Electrophorus and of Electro-static Induction," respecting which the author modifies essentially the ideas hitherto generally received; "The application of the Galvanometer to the study of electric phenomena," in which part of the research Cantoni was assisted by Prof. Brusotti of Pavia; "The relations between the variations of intensity of a current, and those of the temperature in a voltaic circuit;" and other subjects connected with the preceding.—The memoirs of Prof. Vilari relate to "The Influence of Magnetisation on the Electric Conductivity of Iron and Steel; the Currents induced between Iron and other Metals; the Heat developed by Caoutchouc when submitted to Traction;" and in association with Dr. Marangoni, on "The limits of perception of Sounds with respect to their duration."

Chemistry.—Prof. Polli, in examining the intimate mode of action of Sulphurous Acid and Alkaline Sulphites on Fermentable Organic Matters, has endeavoured to show that the mode of action of these preparations consists in an isomeric modification of the molecular aggregation, without alteration of the elementary chemical composition.—Prof. Selmi, of Mantua, has communicated his experiments on the miasmatic air of Mantua.

Natural History and Geology.—Under this head there are two botanical memoirs by Prof. Gorovaglio: one on a New Species of Sensitive Plant, cultivated in the Botanic Garden of the University of Pavia; the other containing a project for the establishment of a laboratory of Cryptogamic Botany, with the view of studying the maladies of plants and animals produced by cryptogamic parasites.—In connection with zoology, there is a note by Crivelli and Maggi on the *Corpora fimbriata* of the Frog, and another by Tigri, on the Silkworm Disease.—In Geology, Paolo Garini communicates a paper on a method of producing experimentally the phenomena of Glaciers.—Leopold Maggi communicates his researches on Lacustro-glacial Deposits; and, lastly, Negri and Spreafico have presented a memoir on the Geology of the Environs of Varese and Lugano.

DIARY

THURSDAY, JANUARY 13.

ROYAL SOCIETY, at 8.30.—On the Mineral Constituents of Meteorites: Mr. N. S. Maskelyne.—On Fluoride of Silver: Mr. G. Gore, F.R.S.—Approximate Determination of the Heating Powers of Arcturus and α Lyræ: Mr E. J. Stone, F.R.S.

THE PROJECTED CHANNEL RAILWAYS

II.

To connect England and France by a railway through a submarine tunnel is not a novel idea. From time to time English and French engineers have revived the plan of tunnelling under the Straits of Dover with some modification or other. Among these the latest and most carefully considered proposition is that by Messrs. Hawkshaw, Brunlees, and Low, in connection with Messrs. Talabot, Chevalier, and Gamond. The scheme of these engineers will be best understood from their report to a committee of promoters, and we will give those passages of the report which are essential for the clear comprehension of the plan :—

"The undersigned engineers, some of whom have been engaged for a series of years in investigating the subject of a tunnel between France and England, having attentively considered those investigations and the facts which they have developed, beg to report thereon jointly for the information of the committee.

"These investigations supported the theory that the Straits of Dover were not opened by a sudden disruption of the earth at that point, but had been produced naturally and slowly by the gradual washing away of the upper chalk ; that the geological formations beneath the Straits remained in the original order of their deposit, and were identical with the formations of the two shores, and were, in fact, the continuation of those formations.

"Mr. Low proposed to dispense entirely with shafts in the sea, and to commence the work by sinking pits on each shore, driving thence, in the first place, two small parallel driftways or galleries from each country, connected at intervals by transverse driftways. By this means the air could be made to circulate as in ordinary coal-mines, and the ventilation be kept perfect at the face of the workings.

"Mr. Low laid his plans before the Emperor of the French in April 1867, and in accordance with the desire of his Majesty, a committee of French and English gentlemen was formed in furtherance of the project.

"For some years past Mr. Hawkshaw's attention had been directed to this subject, and ultimately he was led to test the question, and to ascertain by elaborate investigations whether a submarine tunnel to unite the railways of Great Britain with those of France and the Continent of Europe were practicable.

"Accordingly, at the beginning of the year 1866 a boring was commenced at St. Margaret's Bay, near the South Foreland ; and in March 1866 another boring was commenced on the French coast, at a point about three miles westward of Calais ; and simultaneously with these borings an examination was carried on of that portion of the bottom of the Channel lying between the chalk cliffs on each shore.

"The principal practical and useful results that the borings have determined are, that on the proposed line of the tunnel the depth of the chalk on the English coast is 470 feet below high water, consisting of 175 feet of upper or white chalk and 295 feet of lower or grey chalk ; and that on the French coast the depth of the chalk is 750 feet below high water, consisting of 270 feet of upper or white chalk and 480 feet of lower or grey chalk ; and that the position of the chalk on the bed of the Channel, ascertained from the examination, nearly corresponds with that which the geological inquiry elicited.

"In respect to the execution of the work itself, we consider it proper to drive preliminary driftways or headings under the Channel, the ventilation of which would be accomplished by some of the usual modes adopted in the best coal mines.

"As respects the work itself, the tunnel might be of the ordinary form, and sufficiently large for two lines of railway, and to admit of being worked by locomotive engines, and artificial ventilation could be applied ; or, it might be deemed advisable, on subsequent consideration, to adopt two single lines of tunnel. The desirability of adopting other modes of traction may be left for future consideration."

This, then, is the great Tunnel scheme, which a committee of promoters and engineers submitted to his Majesty the Emperor of the French in June 1868 ; and we are informed "His Majesty was pleased to refer the matter to the favourable consideration of his Excellency the Minister of Public Works, who appointed a special commission to inquire into the subject in all its bearings." This special commission reported in March 1869 ; and a summary of this report on the main question is contained in the following three resolutions, viz.—

"I. The commission, after having considered the documents relative to the geology of the Straits, which agree in establishing the continuity, homogeneity, and regularity of level of the *grey chalk* between the two shores of the Channel,

"Are of opinion that driving a submarine tunnel in the lower part of this chalk is an undertaking which presents reasonable chances of success.

"Nevertheless, they would not hide from themselves the fact, that its execution is subject to contingencies which may render success impossible.

"II. These contingencies may be included under two heads : either in meeting with ground particularly treacherous—a circumstance which the known character of the grey chalk renders improbable ; or in an influx of water in a quantity too great to be mastered, and which might find its way in either by infiltration along the plane of the beds, or through cracks crossing the body of the chalk.

"Apart from these contingencies, the work of excavation in a soft rock like grey chalk appears to be relatively easy and rapid ; and the execution of a tunnel, under the conditions of the project, is but a matter of time and money.

"III. In the actual state of things, and the preparatory investigations being too incomplete to serve as a basis of calculation, the commission will not fix on any figure of expense or the probable time which the execution of the permanent works would require."

Having laid before our readers the Channel Tunnel Scheme in the words of the originators, we shall now proceed to analyse it, and for the purpose we also publish a map forming part of the engineers' report, and which we reduce to a scale of six miles to one inch.

The first important statement with which we meet in the engineers' report is that under section 2, viz., on the theory of the formation of the Straits of Dover. We admit that in all probability the Dover Channel was not produced "by a sudden disruption of the earth at that point," but we cannot endorse the hypothesis that it has been formed by gradually washing away the upper chalk.

In order that the chalk may be washed away more at that point than at others, it is necessary that the current should be stronger. To begin with the operation of washing away, we must have a current, a strong current, which could only flow in a valley or channel, previously formed either by depression of the surface or by the elevation of the land adjoining that surface. Whichever way we take it, the original channel of Dover must, it would seem probable, have been formed by a geological disturbance of the earth's crust.

The current within that geologically-formed channel may have further deepened it, although this is not probable, because at the bottom of a channel from 100 to 200 feet deep, the speed of a current can be but a small fraction of its superficial velocity, and this fraction is assumed to have abraded chalk rock.

Looking at the chart attached to the report of the engineers, we find a series of lines running from the English to the French coast, which are assumed to indicate the position of the strata of various rocks—of the same rocks which compose the hills on either side: so, for example, the district A between the dotted lines is assumed to be that of the upper or white chalk; B, the lower or grey chalk; C, to be the place of a series of strata, such as the upper green sand; the gault, the Folkestone, Sandgate, and Hythe beds; Atterfield clay, &c., &c.

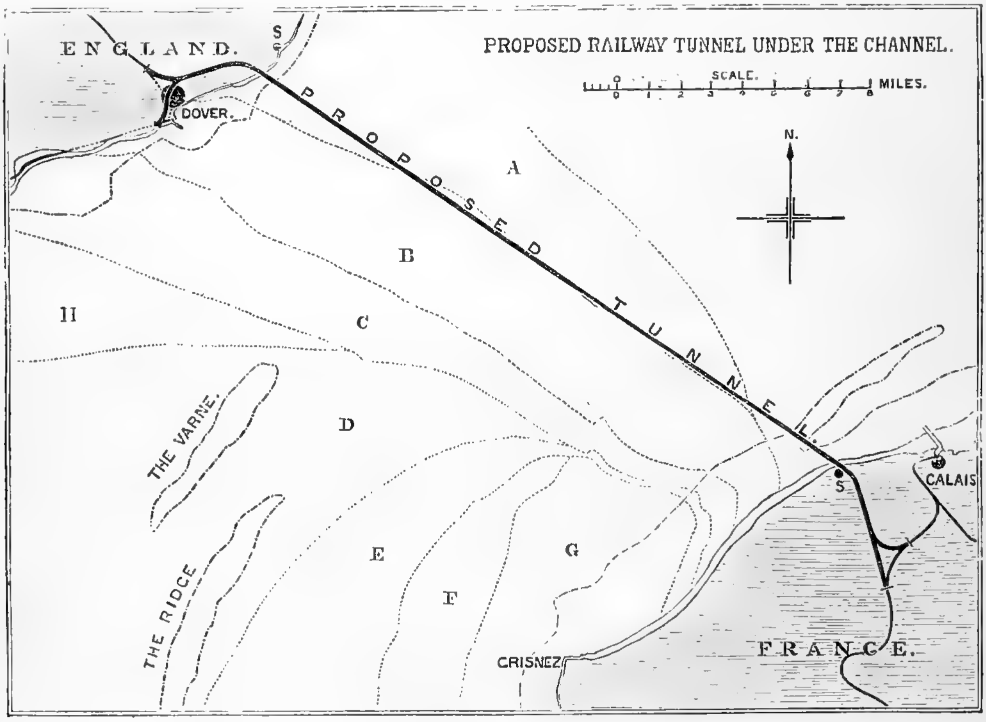
The only question that presents itself to our mind is, whether this chart be correct; whether the geological lines there indicated are the result of test and observation, or whether those lines are based on the theory of the engineers, that the strata of the hills on either side of the Channel pass "undisturbed" in plane surfaces across the Channel, assuming that the strata which formerly occupied the Channel were cut away or carried off; and whether the lines indicated on the map may not principally have been produced by constructing the intersections of those inclined surfaces with the present bottom of the Channel. We fear the geological lines of the diagram were mainly obtained on the above theory of the engineers, and will therefore in a great measure be imaginary.

It is probable that the strata which form the hills on either side will also form the bottom of the Channel, at a different elevation; but it would be rash to say how much the difference might be. It will probably vary across the Channel, the thickness of the strata remaining nearly the same; so it may be presumed that chalk will be found within the Dover Straits at certain depths below the bed of the Channel. If this be so, it would not be necessary to divert the tunnel as indicated on the plan. Nothing short of an actual test across the Channel on the line selected for a tunnel could, however, settle the question of stratification, and determine at what depth a special kind of rock, suitable for tunnelling, would be met with.

The operation of driving the tunnel would have to be carried on many hundred feet below the mean level of the Channel, and, apart from other difficulties attending the execution of such an immense tunnel, for which we have no precedent even on a small scale—the first question would be, whether it may be reasonably expected that tunnelling would be practicable under such circumstances without meeting with an insurmountable influx of water.

That we should meet with many fissures and cracks is a matter of course, for it would be difficult to select on a rocky surface a few square yards without indications of fissures. That water will find its way along cracks we know from experience, and as in this instance no water-tight strata intervene between the sea and the rocky material through which it is proposed to drive the tunnel, so, consequently, we must expect that the work of driving the driftways and the tunnel would be "wet." Although the work may be very wet, it will still remain a question of quantity, and not only one of quality; and, accordingly, we must ascertain whether the quantity of water that might find its way into the workings would be unmanageably large.

On this point a great deal of misconception may be found in "professional" papers. It is asserted, that the



.... Geological Line.
— — — — — — Ten Fathom Line.

A, upper or white chalk. B, lower or grey chalk. C, upper green sand, gault, Folkestone, Sandgate, and Hythe beds. D, region probably occupied by the Hastings sands. E, Neocomian sand. F, Portland stone and sand. G, Kimmeridge clay. H, Weald clay. SS, Borings.

pressure due to a column of 400 or 500 feet of water—which is equal to about 200lb. per square inch—would not only cause infiltration through fissures and cracks, but would in a short time enlarge them, abrade the very rock, and so day by day increase the flow into the driftways. As a general assertion, this evinces a confusion of the static with the dynamic laws of hydraulics.

If we stop the flow from a crack, and if the water cannot be diverted, the full hydrostatic pressure due to the whole column will be established at the very margin of the crack where it was artificially closed. But if we do not stop the flow from it and allow the discharge, the pressure at the margin within the tunnel will by no means be equal to the full hydrostatic column; for, in passing water along a fissure with a certain velocity, by far the largest part of that column will, under ordinary circumstances, be destroyed or consumed in overcoming the friction of the water over the large area of the fissure, and, as a rule, the effective pressure at the end of a fine crack within the tunnel would be only a small fraction of the whole column of water—probably not one per cent., so that no abrasion could take place, and the flow of the water, whatever it might be, would not increase day by day.

This being a very important question in reference to the proposed tunnel, let us take an example.—Assume a fissure 1 yard long and $\frac{1}{1000}$ part of an inch wide—about the thickness of tissue paper. Let this fissure continue in a vertical direction for a distance of 100 yards, to the bottom of the channel, and assume above that fissure 30 fathoms of water. What quantity of water will find its way through that fissure, and what will be the pressure at its margin within the Tunnel? We assume a clear opening throughout, and yet that fissure could only pass 4 gallons per hour into the tunnel, and the effective pressure at its margin would only be $\frac{1}{300}$ lb. per square inch. The effect of such a crack or opening would therefore be quite insignificant. Let all the circumstances remain the same, but assume the fissure 10 times as wide, viz., $\frac{1}{100}$ part of an inch in the clear: it would then pass into the tunnel 136 gallons per hour, with a marginal pressure of $\frac{1}{25}$ part of a pound per square inch; let it be $\frac{1}{10}$ inch wide in the clear, and it will pass 4,392 gallons per hour, with a marginal pressure of $\frac{2}{5}$ of a pound—and if we assume the fissure 1 inch wide in the clear, it will pass 139,905 gallons per hour, with a marginal pressure of $4\frac{1}{5}$ pounds per square inch.

It then becomes chiefly a question of the *nature* of the fissures with which we may have to deal, and while a fine crack one yard long would only admit an insignificant volume of water into the tunnel, a similar crack one inch wide would be a serious matter, very few of which would drown the drift. But even in the latter case no abrasion of the rock could take place, for a pressure of four pounds per square inch has no effect upon chalk.

But though the fissures within the driftways might be very fine, each passing or oozing out a comparatively small quantity of water, easily to be dealt with within a moderate length of the driftways, their number within a distance of twenty-two miles would be legion, and, we believe, would overpower all appliances. These fissures should not be permitted jointly to send water into the driftways; they should be closed as soon as practicable. How is that to be done? By keeping a water-tight main tunnel close upon the face of the driftway. As soon, however, as the cracks would be closed by the main water-tight tunnel, the full hydrostatic pressure of many hundred feet would be resting on it. The main tunnel would collapse unless it could bear a pressure of about fifteen tons per square foot on its superficial area. This circumstance determines the form and the material of the tunnel. It could not be an ordinary tunnel in any sense. Its form must be circular, and its principal material iron. No brickwork could stand that pressure at whatever thickness, within practicable limits, it might be assumed, because by increasing its thickness its superficial area would also increase. Nor could any brickwork be water-tight against such pressures, and, unless it be so, water will find its way into the tunnel very nearly as fast through the lining as without it.

We cannot, therefore, help differing from the resolution of the engineers that—

"In respect of the execution of the work itself, we consider it proper to drive preliminary driftways or headings under the channel, the ventilation of which would be accomplished by some of the usual modes adopted in the best coal-mines."

We consider this resolution fraught with danger. The driftways could never be accomplished without the aid of the main tunnel; nor would the proposed ventilation through the driftways be adequate. Why should the ventilation be similar to that adopted in our best coal-mines? Is the proposed tunnel to be driven through the coal measures? No, it is to be through the grey chalk, and a ventilation which may be adequate in coal measures would certainly fail in the chalk, from which a large amount of an irrespirable gas would exude. This is another reason why the main tunnel should be kept closely behind the face of the driftway, viz., to exclude the surface of the chalk. And why have two driftways to begin with? Moreover, there is no difficulty in sending into the tunnel through ordinary piping, to the face of the heading, ten times as much pure air by mechanical power as the best mode of ventilating coal-mines could possibly ensure.

The tunnel could only be worked by pneumatic pressure: this is obvious from recent investigations of eminent engineers; it could not be for a double line, because that system is not applicable to it; and the old atmospheric plan failed above ground.

We are of opinion that it is not an unreasonable proposition, to drive a tunnel under the Channel, but that in some measure it must be a venture. If we are to undertake such a venture to gain a magnificent prize, of immense value to the English and French nations, we must be prepared to meet all ordinary eventualities, and we must not fail in the attempt by want of foresight, energy, and by dint of proper means. It will cost a great deal, but not too much, with proper management and a little good fortune. The first step towards accomplishing the object would be to obtain a geological section across the Channel, on one, or perhaps on several lines; not a section constructed upon certain theories and assumptions, but one obtained from actual test of the materials which compose the bed of the Channel, following Mr. Hawkshaw's steps on shore also across the Channel, for which purpose the assistance of the Governments of England and France may be confidently expected.

DR. BALFOUR STEWART'S METEOROLOGICAL BLOCKADE

IMAGINE a line drawn round any district, and consider all the air that passes over that line outwards and inwards in any time. Let the whole quantity of vapour of water carried across the boundary line by this air be determined. If during any particular interval of time there is just as much vapour carried outwards as inwards, there must be in that interval either no rainfall on, and no evaporation from the district, or there must be just as much rainfall as evaporation. If more vapour is carried out than in, there must be more evaporation than rainfall. Or, if more vapour enters than leaves, the difference falls in excess of rain above evaporation.

Dr. Stewart proposes to establish a *cordon* of meteorological stations, and to arrange a reduction of observations taken at them, so as to keep, as far as possible, an exact account of the quantity of vapour entering and leaving the space over the surrounded district. This appears to me a most valuable proposal, which, if well carried out, must have a very important influence, tending to raise meteorology from its present empirical condition to the rank of a science. The object of the present notice is to suggest that the same system of account-keeping ought to be applied to electricity.

Whatever we may think as to the nature of electricity, it certainly has, in common with true matter, the property of being invariable in quantity. This property is conveniently enough expressed, as it were, mechanically, by the one-fluid hypothesis, which asserts that positive or negative electrification of any piece of matter consists in the presence of more or less than a certain quantum of the electric fluid; that quantum being the amount possessed when the matter in question exercises no attractive or repulsive force, varying with artificial variations of the electric condition of the testing body presented to it. On this hypothesis, "quantities of electricity," positive and negative, are excesses of the quantity of the hypothetical fluid above or below the "quantum" corresponding to zero of the electric tests.

The ordinary fair-weather condition in our latitudes presents us with negatively electrified air in the lowest stratum, extending at least as high as our ordinary houses above the surface of the earth; and positive electricity of greater amount, on the whole, in the higher regions. The atmospheric electrometer indicates in absolute electrostatic units the total quantity of electricity in the atmosphere, over a certain area of the place of observation; being the excess of the amount of positive above the amount of negative electricity in the whole column. This excess in fair weather is generally positive. The fact that it is not the electricity in the lower regions alone, but an effect depending on the whole electricity of the atmosphere from lowest to highest, that is the thing observed in the ordinary observation of atmospheric electricity, renders this subject more suitable even than moisture for the application of Dr. Stewart's blockade. Thus, the hygrometrical blockade is complete only if both moisture and the effective component of wind are known at all heights above the surface; the electrical blockade is complete when, besides the electrometer measurements at the observatory, the effective component of the wind at all heights is known. But among the many unknown quantities involved, the two departments of the blockade combined will give means for eliminating some and estimating others for which the hygrometrical blockade alone, or the electrical one alone, would be insufficient.

WILLIAM THOMSON

THE SCENERY OF ENGLAND AND WALES

The Scenery of England and Wales, its Character and Origin. By D. Mackintosh. (Longmans and Co.)

READERS of some of the geological journals are sufficiently acquainted with the name of Mr. Mackintosh. They know him as a writer who, for the last four or five years, with wonderful perseverance, has kept on enunciating certain views of denudation which he has adopted. His papers, however, do not suggest that their author possesses the large grasp of the subject, the range of acquirement in geological studies, and the gifts of style which must necessarily belong to the man who would successfully expound the history of the scenery of the country. The task is a difficult one—much more difficult than even geologists themselves usually believe—and the announcement that it had been undertaken by Mr. Mackintosh probably took a good many readers by surprise. They could not but award him the credit of great boldness, whether or not they found, on examination, that he deserved also the praise of success.

Mr. Mackintosh, as a writer on geological subjects, is under the influence of one dominant idea. He believes in the Sea, the whole Sea, and nothing but the Sea. It seems to haunt him like a nightmare. To his ear all sounds in Nature are drowned in the thunder of waves, the rush of ocean-currents, the beating of multitudinous billows, that batter and grind the solid substance of the land. A mist of ocean spray is ever in his eyes. He can but dimly see that any other powers are at work around him save the everlasting breakers. The fall of rain, the roar of rivers, the silent majesty of glaciers and snowfields, have little charm for him, and can never wean his affections from his first love. He can be brought to turn his thoughts neither to the right hand nor to the left, but keeps his eye stedfastly fixed on the one grand object of his faith and adoration. If, indeed, for a moment the contending claims of some other power in Nature obtrude too pertinaciously upon his notice, he clings to some bigger wave, or dashes into some stronger ocean-current until the temptation has passed away.

It is seldom that we meet with one governing idea so unflinchingly followed to the exclusion of anything and everything which might modify it; seldom that we encounter mental colour-blindness so thorough as to admit of the discrimination of apparently but one hue. Not merely does he everywhere and always reiterate that "the greater part of the land surface, at any given time, must present the form given to it by the sea," but he traces this marine sculpturing down to the minutest details of contour, even though rains and frosts and streams seem to rise up in protest to his face. The tendency unduly to exalt the power of the sea as a geological agent has always characterised the writings of English geologists, probably from the greater prominence which the sea acquires in the eyes of islanders. But the tendency never received such an extreme development as it has done in Mr.

Mackintosh's pages. He complacently remarks that hi views "more or less agree with opinions held by Sir R. I. Murchison, Sir Charles Lyell, Professor Phillips Mr. C. Darwin, and others. This *argumentum ad hominem*, we imagine, will hardly be relished by some at least of these gentlemen. Mr. Mackintosh should remember that if his views are sound, the citation of such names is not necessary, while, if they are erroneous, not all the big names in England can save them from the oblivion to which they are doomed.

The author of this volume has evidently never travelled. He tells us, too, that he purposely refrained from reading until his views were formed, "lest a bias should be given to his opinions." And his reading, since these unbiassed opinions were elaborated, appears to have consisted mainly of the recent journals and magazines in which he himself has been writing. And yet a man without travel, and without reading, sits down to write a book on the character and origin of the scenery of a country! He has taken his own little corner of the earth and framed his theory out of it, forgetful of the wide world outside, which must be studied as a whole, if one would well understand any part. While reading the book with laudable perseverance, we have had four lines of "Don Juan" constantly suggesting themselves, where the poet describes a certain easy-minded old gentleman as one who

"Saw with his own eyes the moon was round,
Was also certain that the earth was square,
Because he had journeyed fifty miles and found
No sign that it was circular anywhere."

We presume that Mr. Mackintosh's views would "more or less agree" with those of this philosopher as to the shape of the moon, and generally as to matters of fact regarding which there can be no dispute. Like the same worthy, too, he does not take things on trust. He uses his own eyes and draws his own inferences. He is certain of his convictions, because he has journeyed so many miles and found no sign that these convictions could be anything but true. Unfortunately, however, he has either made his journeys with a foregone conclusion in his mind, or they have been too limited to enable him fully to understand what the subject really is of which he proposes to treat; or, what is probably the truth, he lacks that grounding in exact knowledge of geological structure which is absolutely necessary to one who wishes to elucidate the history of a land surface.

So much for the general purpose of the volume. Its plan and execution are sadly unmethodical. It is divided into three books; but, in spite of the explanation of this arrangement given in the preface, it is not easy to trace any clear distinction in the subjects of the divisions. The reader is jerked from one topic to another, getting of some of them the merest glimpse, so that after a little he begins to experience something of the feeling of unrest which comes over him at another time when he tries to pick out the details of a landscape from the window of an express train. There is no index to the book, and unless a passage is specially noted down at the time of perusal its subsequent recovery is troublesome. Altogether the volume suggests to the reader the idea that he has here a multifarious collection of jottings and excerpts from note-books, strung together with not much reference to their connection. For example, the First Book, according to the table of contents, consists of "Introductory remarks on the causes of denudation and origin of natural scenery in various parts of the world." Under this comprehensive title come just twenty-one pages, in which a word or two are said about faults and fractures, the fact that rains, frosts, rivers, and glaciers are denuding agents is alluded to and not denied, while about fourteen pages, or two-thirds of Book I., are devoted to desultory remarks on sea-bottoms, Irish eskers, oceanic currents, waves in Norway, waves in Shetland and Caithness, waves on the coast of Ireland, sea escarpments in Ireland, remarks on Irish cliffs, sea-coast cwms in Ireland, beachless shores, denudation of Norway, denudation of South America and Australia. This introduction is really a very fitting one to the rest of the book. It shows how the hue of the author's spectacles not only colours all his own observations, but will not let him see the true tint of the observations of other people. For instance, he professes to condense from Forbes's work an "account of the most striking physical features of Norway, *excepting those resulting from glacial action.*" *Hamlet* with the Prince of Denmark omitted was nothing to this. If there is one country in the world more marvellously eloquent of glacial action than other countries it is Norway. That is the one grand physical feature of the peninsula; every fjord, every fjeld points to the grinding power of ice. Yet a writer on denudation, anxious as to the impartiality of his views, ventures to write about the sculpturing of the present physical features of Norway, and to pass the glaciers and snowfields by. Again, he cites Australia as a recently emerged area, where there cannot have been any "long-continued action of rains and streams." But he takes no note of the old river gravels, with cappings of basalt, hundreds of feet above the level of the present streams, which point to the passage of a vastly protracted period of subaërial erosion.

Perhaps no passage in the book shows better the author's obliquity of vision, and his consequent (though no doubt unintentional) unfairness, than one in this same introductory chapter, where, in lieu of giving the reader a general view of what denudation is, he states, on the authority of Mrs. Somerville, that a tidal current in the Shetlands runs at the rate of fifteen miles an hour, while "*the average velocity of the river Rhone is not a mile and a half an hour.*" No one unacquainted with the subject would be likely to escape the inference which the writer probably intended should be drawn, that even a rapid river like the Rhone has not more than a tenth of the erosive power of some marine currents. Now, though there can be no doubt that some of the most rapid currents known flow among the Orkney and Shetland Islands, yet we take leave to question whether any of them ever reach by any means so high a velocity as fifteen miles an hour. Yet even granting that they do, they are quite exceptional, and it was long ago shown by Dr. Fleming that their erosive power over a surface of rock is nearly, if not wholly, *nil*, for they cannot even rub off the crust of tender barnacles. But to set down the average velocity of the Rhone as "not a mile and a half an hour!" Shade of old Rhodanus! have mercy upon Mr. D. Mackintosh if that gentleman ever gets near enough the "rushing of the arrowy Rhone." A mile and a half an hour! why, that is a very feeble velocity for most of our comparatively sluggish British rivers. The Thames flows at the rate of two or three miles an hour, the Severn at three or four miles, and most of our upland streams run still faster. Surely there is just cause of complaint against a writer who, in support of a theory which he has adopted, cites facts which are wholly exceptional without saying that they are so, while at the same time he is led in his ardour unconsciously to misstate the facts which do not tell in his favour.

We have read this book with a feeling of regret that it should ever have been published. Its author is evidently a hard-working observer, and perhaps had he been less ambitious, and been content to wait some years longer until his experience had widened, and he had found time to mature and methodise his opinions, our verdict upon his labours might have been different. As it is, he has hastened before the world with a book of which, in a year or two hence, no one will see the crudity more keenly than he will do himself. A work which aims at giving a popular version of any branch of scientific inquiry should be eminently clear, accurate, and readable. Mr. Mackintosh's volume fulfils none of these conditions, and we only fear that its effect may be to discourage readers from seeking to learn more of what is in reality one of the most fascinating fields of geology.

OUR BOOK SHELF

Medical Chemistry.—*Manuel de Chimie Médicale et Pharmaceutique.* Par Alfred Riche. 8vo., pp. 771, figures 104. (Paris: Germer-Baillière, 1870. London: Williams and Norgate.)

We have here a comprehensive text-book of chemistry, in which the medical and pharmaceutical applications of the science are specially noticed. The author is one of the professors in the School of Pharmacy at Paris, and the "mineral chemistry" of the manual is essentially a reproduction of his course of lectures. The "organic chemistry" is based on the course of Professor Berthelot, and the toxicological portions of the work reflect the teaching of Professor Bouis. Though designed for the use of students of medicine and pharmacy, this manual is primarily a systematic exposition of the fundamental facts of chemistry, and its technical character is revealed only in incidental explanations. Thus, sulphuric acid is noticed with the oxygenated sulphur compounds, and its properties, preparation, commercial manufacture, purification, and chemical constitution, receive adequate treatment before its medical employment and its action as an irritant poison are considered. Again, in the section on the natural alkaloïds we get the chemical history of each of the more important opium bases before we obtain any information respecting the assay of opium, the action of the drug on the human system, or the symptoms of poisoning by opiates. The officinal processes for preparing the chemical substances used in medicine are plainly but briefly described, and practical directions are given for testing the purity and estimating the strength of commercial products. The author has devoted 150 pages to "biological chemistry," an important section of the science which receives scant notice in most manuals, and has minutely described methods of analysing milk, blood, urine, and calculi, which may be adopted by the physician to obtain trustworthy indications of the progress of disease or the effects of medicines. Professor Riche's manual has so many good qualities that we reluctantly call attention to a characteristic which detracts from its value as a treatise on general chemistry. While admitting that the modern or molecular notation is preferable to the notation based on the old equivalents, the author deliberately rejects the former "because it is not yet recognised in the official programmes." Consequently, the book is filled with symbolic formulæ which do not accord with accepted theories. In the introduction to the "organic chemistry," M. Riche attempts to adapt the exoteric notation of his school to modern ideas by doubling the symbols of oxygen, sulphur, and carbon; but English students will look with little favour on the hybrid formulæ thus produced. We trust that the author will burst his bonds of red tape before the second edition of his manual is issued. J. C. B.

Heads and Tales; or, Anecdotes and Stories of Quadrupeds and other Beasts, chiefly connected with Incidents in the Histories of more or less Distinguished Men. By Adam White, late Assistant in the Zoological Department, British Museum. (London: Nisbet and Co. 1870.)

The idea of bringing together the anecdotes of animals recorded in the biographies of great or well-known men is a good one; but the notion of interlarding these anecdotes with facetiæ selected chiefly from Mr. Mark Lemon's "Jest Book" can hardly be commended. Mr. White is sadly mistaken if he supposes that well-written stories of animal life require to be made palatable to school-boys by the addition of puns and shallow witticisms. Schoolboys may well be amused at the solemn way in which the author announces his discovery (in the pages of Macaulay) of the cause of the death of William III.; but they will think it beyond a jest when they themselves discover that six pages which should have been filled with anecdotes are occupied by Macaulay's account of the last days of King William. Mr. White does not exclude man from what he is pleased to term his anecdotical treatment of the great order Mammalia. Three stories of a ludicrous character, however, suffice to illustrate the human species. The schoolboy reader is duly warned against the theory of the genesis of man by natural causes in the following terms:—"Let us never for a moment rest in such fallacious theories, or accept the belief of Darwin and Huxley, with a few active, agitating disciples, that animals, and even plants, may pass into each other. Darwin and Huxley cannot change nature. They may change their minds and opinions, as their fathers did before them. It is, we expect, only the old heathen materialism cropping out." This extract is, perhaps, sufficient to show the author's mental calibre. It is not necessary to praise the illustrations of this book; it is quite sufficient to mention that they are from the drawings of J. Wolf.

Facts and Dates; or, The Leading Events in Sacred and Profane History, and the Principal Facts in the various Physical Sciences: the memory being aided throughout by a simple and natural method. By the Rev. Alex. Mackay, LL.D. (Blackwood and Sons.)

A so-called system of mnemonics may possibly be of use to young men cramming history and geography for competitive examinations; but we see no room for it in science-teaching. The scientific facts capable of being expressed by numbers, and which it is desirable to commit to memory, are really very few. Indeed, we believe they are so few in any given science, that it would take most people longer to master Dr. Mackay's system of artificial memory than to learn the numbers themselves. The author has spent a good deal of labour in so framing his mnemonic sentences as to contain ideas having some connection with the fact intended to be remembered. This is all very well; but the essential fault of his system, and of every such system, is, that it is not sufficient to remember the *idea* contained in the mnemonic sentence: every word of it must be accurately retained. We are sorry to see that Dr. Mackay is sadly afflicted with the Great Pyramid craze. The introduction of such a matter as the pretended scientific revelation into a book intended for school use is very much to be deprecated.

SENSATION AND PERCEPTION
II.

THE doctrine that there is a distinct organ for the realisation of Sensations only, apart from that for Perception, has been very generally taught, and has been insisted on by no one more strongly than by Dr. Carpenter in his otherwise most able and suggestive expositions of nervous physiology. He says:* "The general rule of action appears to be that the impressions made by external objects upon the afferent nerves, when transmitted to the spinal cord, ascend towards the cerebrum without exciting any reflex movements in their course. When such an *impression* arrives at the sensorium,† it excites the consciousness of the individual, and thus gives rise to a *sensation;* and the change thus induced being further propagated from the sensory ganglia to the cerebrum, gives occasion to the formation of an *idea.*" And that Dr. Carpenter here means by the word 'idea' what we have previously spoken of as that complex intellectualised sensation generally called a 'perception,' seems obvious from the following passage occurring on another page, where the same author says: "It is further important to keep in mind the distinction between the *sensations* themselves and the *ideas* which are the immediate results of those sensations when they are perceived by the mind. The ideas relate to the *cause* of the sensation or the object by which the impression is made" (p. 711). But since, in Dr. Carpenter's view, the sensory ganglia constitute the *sensorium*, in which impressions become conscious sensations; and because he naturally thinks it very improbable that there are two distinct organs of consciousness, he is compelled to adopt the hypothesis that the superficial grey matter of the cerebral hemispheres, in which intellectual operations are principally carried on, is not itself endowed with the function of consciousness. Thus he assumes—as the most probable inference to be drawn from various kinds of evidence—"that the sensory ganglia constitute the seat of consciousness not merely for impressions on the organs of sense, but also for changes in the cortical substance of the cerebrum; so that until the latter have reacted downwards upon the sensorium we have no consciousness either of the formation of ideas or of any intellectual processes of which these may be the subject."‡ And, although we are quite unable to agree with the conclusions themselves as to the absence of consciousness in connection with the activity of the cerebral hemispheres, and as to its presence as a functional attribute of the sensory ganglia alone, still it is sufficiently interesting, in a philosophical point of view, to find Dr. Carpenter declaring so confidently in favour of a distinct organ of consciousness, even altogether separate from those parts of the cerebral hemispheres in which what we have called § *potential knowledge* is produced—meaning by this term what is called knowledge, so far as it can exist *minus* the attribute of consciousness. The elaboration of this potential knowledge is, in fact, a process the possibility of which has been ably discussed by Dr. Carpenter in the section in which he speaks of "unconscious cerebration."

We must, however, briefly inquire into the reasons which have induced Dr. Carpenter to regard these so-called sensory ganglia as the seat of consciousness; though, before doing so, it will be well to draw the reader's attention to the following considerations. As it is quite true that different nerves, coming from the sense organs or surface of the body generally, do pass through the sensory ganglia on their way to the higher centres in the cerebral hemispheres, it is obvious that the impressions made upon any one of these lower centres must be *qualified* to a certain extent, inasmuch as they are the middle terms of a series, and therefore are related to their antecedents and to their consequents in the same way that these are related to one another—the antecedents being the external impressions, and the consequents the resulting perceptions. For, when an impression of a certain kind is made upon any given part of the surface of the body, this impression traverses definite nerve-fibres, in order to reach functionally related portions of the cerebral hemispheres, and so we may well suppose that the fibres, on their way, must necessarily pass through *definite parts* of the sensory ganglia, and produce, in certain of the ganglionic elements there situated, impressions of a *definite kind.*

Thus, therefore, although we may believe that no state of consciousness is aroused by this molecular action taking place in these lower sensory ganglia, the impressions made upon them may be, nevertheless, definite enough in kind and place to ensure a partial transference of such molecular movement along given and accustomed outgoing motor channels; such organic possibilities of motorial response having been slowly built up and elaborated, in past time, under the guidance of then co-existing and related conscious states. Thus, movements may at times be produced in every way similar, as regards mode of origin, to those automatic or reflex movements occurring through the intervention of the spinal cord alone; though they may be as much more complex, and apparently purposive, as these higher centres are more complex than the spinal centres. And it is, we think, because the movements are produced by reflections from the highest motor centres, *whose complexity renders the most purposive movements possible*, that such movements have been supposed to be invariably the sequences of conscious impressions or *sensations*, and have hence received the appellation of *sensori-motor.* This name, however, begs the question in dispute—as to whether impressions reaching thus far would be revealed in consciousness or not; and from what has been already said it will be seen that in the settlement of this question we must not rely too much upon the purposive nature of the movements as evidence that they are the results of conscious impressions. Reasonings of this kind led Pflüger to suppose that the spinal cord was also a seat of consciousness.

We quite agree with Dr. Carpenter* and others, however, in the opinion that the organic possibilities of executing all combined muscular movements of which the individual is capable, reside in the spinal cord and medulla, and also still higher in the motor centres in immediate connection with these so-called sensory ganglia—by virtue of definite nerve connections therein established. So that all the facts with which we are acquainted, as he says, "tend strongly in favour of the view that even voluntary movements are executed by the instrumentality of the automatic apparatus, and that they differ only from the automatic or instinctive in the nature of the stimulus by which they are excited." This doctrine may be aptly illustrated by reference to the act of coughing, since this is an instance in which a complicated set of movements usually produced automatically may nevertheless be incited by a voluntary determination. When so produced, the will is directed to the production of the result as a whole; no attempt being made to single out the different movements, and then to combine them; so that, as Dr. Carpenter also says, "the will thus seems obviously to take the place of the laryngeal or tracheal irritation as the *primum mobile* of the series, which, in its actual performance, is as automatic in the latter case as in the former." In each case, the same organised set of nerve connections in the higher motor centres (constituting the organic representatives of the combined muscular movements of the act of coughing) are called into activity; now by a volitional incitation descending from the cerebral hemispheres, and, at another time, as a result of an afferent stimulus reaching the

* Principles of Comparative Physiology, fifth edition, p. 707. 1854.

† Constituted by certain ganglionic structures at the base of the brain, in relation with the various sensory nerves, and usually spoken of as the *sensory ganglia.*

§ See paper on "Consciousness," in *Jour. of Ment. Science*, p. 512.

* Human Physiology, fifth edition, p. 516.

related sensory centres from some part of the respiratory passages themselves.

Bearing these facts in mind, and also the psychological view of the essential unity in the mode of evolution of all sensations or conscious states—whether simple or complex—we shall find that the performance of many acts of the so-called *sensori-motor* type do not necessarily lend such support to the supposition that the sensory ganglia are the seats of consciousness as they have been supposed to do. That the movements of an infant or of an idiot should appear to be automatic in nature, is only to be expected if we consider that they are responses to conscious impressions excited in quite undeveloped cerebral hemispheres, in which, as yet, the possibilities of intellectual and volitional action of the lowest type only are organised. Thus, the only action which at this time could possibly emanate from the operation of the intellectual centres would be such as Dr. Carpenter has supposed to depend upon the stimulus of mere sensations; and it does not at all follow, as he seems to suppose, that such movements are excited by sensations, realised as such in the sensory ganglia and thence reflected without the intervention of the cerebral hemispheres. Neither do we think his doctrine receives any stronger amount of support from the fact of our ability to perform certain *habitual* movements whilst the cerebrum is occupied with some engrossing train of thought.

It is, we think, an altogether improbable assumption to suppose that the so-called "secondary automatic" acts take place, as a general rule, altogether without the intervention of the cerebral hemispheres. Taking the instance cited by Dr. Carpenter, of the individual who, falling into a deep reverie whilst making his way through the streets, nevertheless walks with ease along accustomed routes, though his attention may be entirely absorbed by some particular train of thought, it is supposed that these movements are characteristic instances of *sensori-motor* acts, that they are brought about solely by reflections from some of the sensory ganglia, and without the intervention of the hemispheres. But it seems to us much more reasonable to suppose that the cerebral hemispheres have been concerned to some extent, even though the consciousness of the individual has been otherwise monopolised. In proportion to the frequency of the repetition of such movements—to the degree in which they have become habitual, so can we the more easily understand that the cerebral action involved may take place without arousing consciousness, and so quite independently of trains of thought which are monopolising the person's attention. A motor incitation now really volitional, may, though similar in all other respects, at another time be purely reflex and unconscious, even though passing over from regions of the cerebral hemispheres themselves;* the consciousness or the unconsciousness of the incitation depending upon the particular direction of the attention of the individual at the time being. This view seems rendered all the more probable if we consider what are the effects on man of even small injuries of parts of the cerebral hemispheres above the level of the sensory ganglia. If, in the instance above alluded to, the person maintains the erect position, and even walks perfectly well, through the intervention of nerve-centres no higher than the sensory ganglia, how is it that the same man would be completely paralysed on one side of his body for months or perhaps years by an effusion of blood into, or a softening of, a portion of brain tissue quite above these sensory ganglia—by a lesion, for instance, of a portion of the opposite hemisphere outside its *corpus striatum*? We may set such an individual upon his legs as often as we choose, but no amount of mere sensory impressions are capable of exciting the supposed *sensori-motor* movements; the paralysed limb is utterly powerless, and even the mere attitude of standing, when the individual is unsupported, is found to be impossible.

* See article on "Physiology of Thinking," *Fortnightly Review*, Jan. 1869.

The experimental evidence which has been appealed to is also capable of receiving different interpretations; and, indeed, physiologists themselves have already expressed directly contrary opinions upon this subject. The evidence is, in fact, of such an uncertain nature as to be quite incapable of leading to a very definite conclusion, unless we have formed some decided opinion as to the real nature of a sensation, and as to how this differs from what is called a perception. Flourens denies, for instance, that birds or mammals whose cerebral hemispheres have been removed are any longer capable of appreciating sensory impressions; whilst Magendie, Longet, Vulpian, and many others maintain that such animals are capable of feeling simple sensations, and that they are therefore, to a certain extent, in possession of consciousness. But it may be fairly maintained that the way in which such animals respond to external influences acting upon them are explicable without postulating the existence of consciousness, if we bear in mind that they do still retain their sensory ganglia and all the related motor centres in organic connection with these; and if we bear in mind also what has been already said as to the degree in which impressions, reaching only so far as these sensory ganglia, and not revealing themselves in consciousness at all, are, nevertheless, *qualified*, and therefore capable of exciting those purposive movements which exist potentially in the related motor centres in the form of definite nerve connections. The molecular mobility of these centres has only to be disturbed in order to bring about, with machine-like precision, the natural movements themselves. Longet and Vulpian look upon the *pons Varolii* as the seat of *general sensibility*,* and there certainly seems much more evidence in favour of this view than in support of the doctrine of Dr. Carpenter that such is the function of the optic thalami. Evidence of different kinds seems quite opposed to the latter view; but much *may* be said—even though, as we think, to little purpose—in favour of the opinion of Longet and Vulpian. The *corpora quadrigemina* are similarly supposed to be the seats of perception for optical impressions. And one of the strongest facts that has been recorded in favour of the supposed *sensori-motor* nature of certain movements was observed in a pigeon, which lived eighteen days after its cerebral hemispheres alone had been removed by Longet. When this animal was taken into a dark room, every time a light was brought near its eyes the irides contracted, and often even winking occurred; "mais chose remarquable," Longet says,† "aussitôt que j'imprimais un mouvement circulaire à la bougie enflammée, et à une distance assez grande pour qu'il n'y eût point sensation de chaleur, le pigeon exécutait un mouvement analogue à sa tête." Nevertheless, it is said that this same animal sometimes seemed to avoid obstacles, and sometimes knocked himself against them. So that when we consider how closely the movements of the eyes are bound up with visual impressions generally, this following of the strong light, which seems so much to suggest consciousness, may be capable of explanation without having recourse to such a supposition. Dr. Carpenter has called attention to the fact that when the eyelids are closed, if we attempt to move the eye-balls in any given direction, we can only do this with considerable difficulty, and with an extreme sense of effort—"This sense being the result of the state of tension in which the muscles are placed by the effort to move the eyes without the guiding visual sensation." He then adds:—"Now, on the other hand, the will may determine to fix the eyes upon an object; and yet this

* These conclusions were arrived at from an observation of birds and mammals whose cerebral hemispheres, corpora striata, thalami, corpora quadrigemina, and cerebellum had been all removed, leaving within the cranial cavity only the *pons*, or *tuber annulare*, and the medulla. (Longet, "Traité de Physiologie," 3rd ed. t. iii. p. 156.)

† Loc. cit. p. 428.

very fixation may be only attainable by a muscular movement, which movement is directly excited by the visual sense without any exertion of voluntary power over the muscles. Such is the case when we look steadily at an object whilst we move the head from side to side; for the eyeballs will then be moved in a contrary direction by a kind of instinctive effort of the external and internal recti, which tends to keep the retina in their first position, and to prevent the motion of the images over them." These are said to belong to the category of voluntary movements, and yet we are not ourselves conscious that they are taking place; we know of it only, as Dr. Carpenter says—or rather learn to infer the existence of such movements in ourselves—by observing what takes place in other persons. We must make due allowances, therefore, for facts like these, when attempting to interpret what takes place in animals from whom a part of the brain has been removed; and we must also bear in mind that the endowments of the lower nerve-centres are different amongst different classes of animals, before we come hastily to the conclusion that movements of the kind mentioned in the pigeon were indicative of consciousness on its part; and still more before we conclude from such phenomena that the sensory ganglia in man are also seats of consciousness. As regards motor power, the differences are most notable amongst different groups of animals. Thus, after complete removal of the cerebral hemispheres, fish, reptiles, birds, and the lower mammalia experience extremely little diminution in their powers of movement. Carp and frogs continue to swim as well as before; a pigeon when abandoned in the air flies to the ground, settling lightly on its feet; whilst a rabbit runs away when irritated, performing these movements with no appreciable difficulty, and with only a slight evidence of weakness. The weakness becomes much more notable when the operation is performed upon a dog, though it is less marked in proportion as the animal is a young one. An adult dog deprived of his cerebral hemispheres is, however, no longer capable of maintaining the erect position, though it can still move its legs freely whilst lying down.

The effect in man, of even limited injuries to one or other hemisphere, in producing paralysis of the opposite side of the body, has been already referred to. Such variations must be taken into account in our interpretations of Longet's experiments with the pigeon. But even Longet himself, though he makes the *pons* the centre for general sensibility and the *corpora quadrigemina* the centre for visual sensations, seems, after all, to entertain considerable doubts or to whether he is warranted in making use of the word "sensation." Thus he says: "Certes en prenant le mot *sensation* dans son acceptation rigoureusement métaphysique, et ne l'appliquant qu'à tous les cas d'exercice de la sensibilité avec *conscience*, on devra admettre que la protubérance, siége de la sensibilité générale, et les lobes cérébraux, siége de l'intelligence, doivent nécessairement mettré, pour ainsi dire en commun leur activité, et concourir au même acte." But then he adds, "Mais à la rigueur, ne pourrait-on pas permettre aux physiologistes de distinguer la *perception* simple (en quelque sorte *brute*) des impressions, de l'attention qui leur est accordée, de l'aptitude à former des idées en rapport avec elles?" To this question we would reply that the power of simple perception with which Longet wishes to endow these lower centres is probably not attended by Consciousness, as he himself seems to intimate, and therefore such a word is altogether unsuitable to express that *unconscious discrimination* of impressions, which may be followed by apparently purposive movements, resulting from the excitation of these lower centres. How this unconscious discrimination may occur, and how it may result in definite movements, have been shown.

Thus, we think the experimental evidence leads us to the conclusion that *unconscious* or *organic discrimination* takes place in the sensory ganglia, just as it takes place in the spinal cord; only that the discrimination in the former is of a higher type, and results in the more purposive movements, because it takes place in nerve-centres of higher rank. For the production of a distinct state of feeling or sensation, however, even of the simplest kind, conscious intellect is needed, and this cannot be brought into operation without the conjoint activity of the cerebral hemispheres.

We do not consider that such a conclusion is in the least shaken by the evidence furnished by comparative anatomy, notwithstanding what Dr. Carpenter* says to the contrary. He writes as follows:—"Thus we are led by the very cogent evidence which comparative anatomy supplies, to regard this series of ganglionic centres as constituting the real *sensorium*, each ganglion having the power of rendering the mind conscious of the impressions derived from the organ with which it is connected. If this position be denied, we must either refuse the attribute of consciousness to such animals as possess no other encephalic centres than these, or we must believe that the *addition* of the cerebral hemispheres in the vertebrated series alters the endowment of the sensory ganglia,—an idea which is contrary to all analogy." We feel most surprised that Dr. Carpenter should have expressed this latter view; in the first place, because it is quite adverse to the general doctrines of Von Baer, or, in other words, to the doctrines of Evolution which he has done his best to elucidate; and, secondly, because such a notion is opposed to the information afforded by actual experiment as to the alteration in the endowment of the motor centres (to which we have already referred) in ascending the vertebrate scale. As specialisation of structure occurs, so must we get specialisation of function; and we are glad to find that an idea, long familiar to ourselves, has also occurred to Mr. Herbert Spencer, and has been thus clearly expressed by him†:—"It does not follow, as it at first sight seems to do, that feelings are never located in the inferior nervous centres. On the contrary, it may well be that in lower types [of animals] the homologues of these inferior centres are the seats of consciousness. The true implication is, that in any case the seat of consciousness is that nervous centre to which mediately or immediately the most heterogeneous impressions are brought; and it is not improbable that in the course of nervous evolution, centres that were once the highest are supplemented by others in which co-ordination is carried a stage further, and which, therefore, become the places of feeling, while the centres before predominant become automatic."

The conclusions at which we have arrived have an important psychological bearing. Thus, Herbart in Germany, followed by Sir William Hamilton in our own country, made Cognition or discrimination the fundamental fact of Mind, rather than Sensation or mere feeling (which is regarded as its basis by many others), and it must be confessed that physiological evidence accords with the former rather than with the latter view. In the first place, because no consciousness in the form of sensation can take place without the aid of intellectual activity under the form of cognition or discrimination; whilst, on the other hand, cognition or intellectual action may take place under the form of a mere *organic* or *unconscious discrimination*, without the intervention of consciousness. Thus, in the individual, consciousness or feeling comes to be superadded as an additional accompaniment to certain mere organic discriminations; so that consciousness, without which sensation cannot exist, is secondary, whilst cognition, in the form of unconscious discrimination, is primary. Out of this primary undifferentiated organic discrimination, such as alone pertains to the lowest forms of animal life, there has been gradually evolved that which we know as feeling and consciousness.

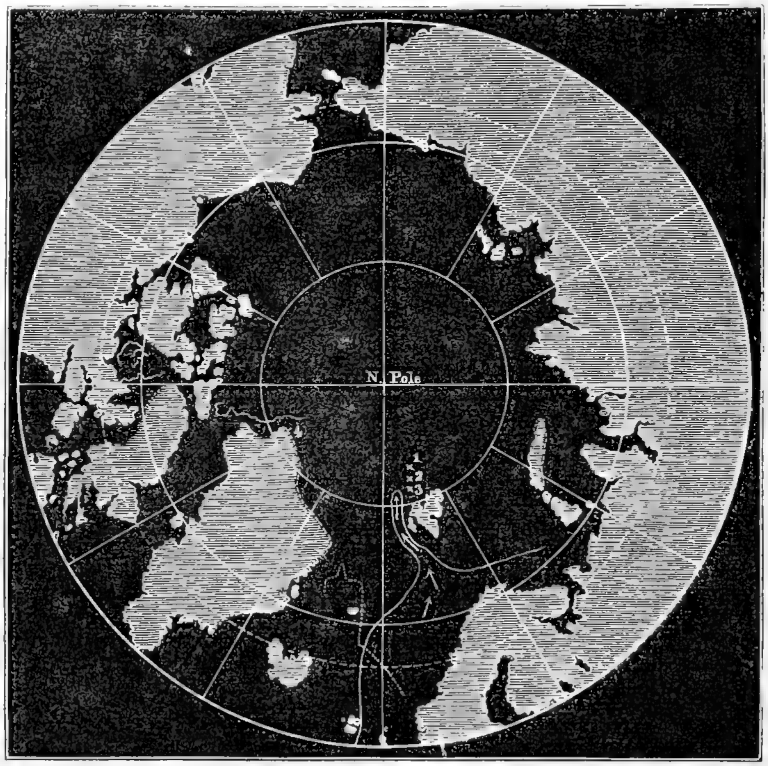
* Op. cit., p. 503. † Principles of Psychology, Oct. 1868, No. 2, p. 105.

THE GERMAN AND SWEDISH EXPEDITIONS TO THE ARCTIC REGIONS

ENGLAND seems ready to resign the position she once held as chief of all the competitors in Arctic exploration. Our flag has been carried within $7\frac{1}{2}$ degrees of the North Pole; our seamen have forced from the ice-bound straits which lie to the north of America the secret of the North-Western Passage; and from the days of Scoresby until those of Franklin we have been foremost in scientific researches within the dreary Arctic wastes. But now the answer to all who would emulate the deeds of a Parry or a Ross, a Beecher or a Franklin, is the stereotyped *cui bono.* A business account of the probable gains of an Arctic journey must be rendered before England will send men or ships to the Polar seas.

In the meantime, Swedish and German explorers are pushing their way boldly into the regions where England won her Arctic laurels—perhaps we ought rather to say, ice-wreaths. Already the most northerly spot reached by our seamen has been all but attained, and there is yet room for supposing that this very year the second German expedition may push its way to the Pole itself. Scientific results of extreme value have also been attained. The course of the Gulf Stream (if Mr. Findlay will permit the name) has been tracked into very high latitudes, its depth has been gauged, and the nature of the currents which run beside it, or beneath it, has been carefully inquired into. The various forms of life which people those Arctic seas have been examined with loving care (extending even to a judicious use of powder and shot, or nets and fish-hooks, as the case might be) by the naturalists who have accompanied the expedition. And lastly, a very important addition, about which I hope to make some remarks on a future occasion, has been made to our knowledge of the variations of the magnetic needle in Arctic regions.



MAP OF THE NORTH POLAR REGIONS

The primary object of all three expeditions has been to attain, if possible, the North Pole of the earth. Dr. Petermann, who had the principal part in planning the German expeditions, has a theory about Greenland, which was associated, perhaps not very fortunately, with the other objects of the German voyagers. But undoubtedly the attainment of the highest possible northerly latitude was their principal aim.

A glance at the accompanying map will show the nature of the Arctic regions, so far as they have yet been explored. The circle 10 degrees from the North Pole has hitherto been crossed in only two neighbourhoods. The figure shows (1) where Parry made his most northerly point in 1827. The Swedish and German expeditions of last year pushed their way towards the same region, and the crosses numbered (2) and (3) indicate the spots they respectively reached. In 1854 Dr. Kane crossed the circle of 10 degrees near (4), having pushed his way along the inlet above the north-western point of Greenland. And in 1865 Dr. Hayes reached the same point, after traversing a large part of Greenland in sledges drawn by Esquimaux dogs.

Notwithstanding the hopes which M. Lambert has formed of attaining the North Pole by passing through the Straits between Asia and North America (shown near the top of the map), there seems every reason for believing that if the North Pole is ever reached by man it must be either along the course pursued by Kane and Hayes, or by the path which Parry followed. In fact, it is reasonable to confine our attention wholly to the latter course, since Dr. Hayes' journey sufficed to show that without the means of crossing the sea, further passage northwards from (4) is impossible, and it is inconceivable that any suitable sea-boat could be carried to (4) either by Kane's or Hayes' route.

The Swedish expedition to (2) is perhaps the most hopeful sea-journey that has yet been made towards the North Pole. They had been engaged until late in the Arctic season in scientific researches on the coast of Norway; yet they succeeded in pushing their way within a few miles of the most northerly point yet reached, and were even then only impeded by the dangers due to the approach of winter. There seems every reason to believe, that had they started a few months earlier they might have pushed their way much further north.

The German expeditions, undertaken in the two years, seem to have followed a course less likely to be successful. Dr. Petermann holds that Greenland extends much further towards the north-west than its shores have yet been traced—nay, even past the Pole, perhaps, to the neighbourhood of Behring's Straits, between Asia and America. Both expeditions sought to reach the north-eastern shores of Greenland with the object of ascertaining whether this theory, or General Sabine's view that Greenland has some such figure as is indicated by the dotted line in the map, is the more correct.

Twice in 1868 Captain Köldewey was forced to abandon this attempt, and each time after his defeat he made for the shores of Spitzbergen. Thus, on July 18, he had already crossed the 80th parallel, and was close to the station marked (3); but thence he again made, by a long *détour*, for the shores of Greenland. It was after his second repulse that he reached his most northerly point (3), close to the most northerly limit of the Swedish expedition.

This year, Captain Köldewey, now in a steamship, has pursued the same tactics, except that he has been less ready to accept defeat, and has persistently sought to penetrate the ice-laden seas which surround the Greenland coast. The dotted line shows the general course of the second expedition; and it will be seen that when last heard of they were close by Greenland, and far south of the 75th parallel. Captain Gray, who brought the latest intelligence of their doings in this neighbourhood, states that on August 1, although the sea was still much encumbered with ice, it was becoming rapidly clearer, so that the *Germania* was likely to have little difficulty in reaching the Greenland coast. I confess, however, that I do not share the hopes which have been expressed of the successful progress of the expedition this year. The result of the expeditions of 1868 seems to point very clearly to another course than that which the *Germania* is now seeking to pursue: and there is nothing in the whole history of Arctic expedition to encourage a hope that a way can be found so far to the west (at least in latitudes below 80°), to the neighbourhood of the North Pole.

The figure indicates the course of the mean summer and autumn isotherm of 3° Reaumer (about 39° Fahr.), in the North Atlantic. Along the course marked by arrows a branch of the Gulf Stream has been traced (in summer) as far north as latitude 81½°; the main stream making its way towards Novaia Zemlia.* Does not Nature herself seem to point out this track past Spitzbergen as the proper course for North Polar explorers? Here, in the first place, the mildest temperature is found; and in Arctic voyaging this is a matter of no small importance. Here also is an assisting current—*valeat quantum valere debet.* But the chief circumstance to be noticed is, that the course followed by the Gulf Stream shows that there is open water—ice-encumbered, no doubt, but still not ice-bound—in this direction. It is well worthy of notice, too, how deep the sea is along this part of the Atlantic. Herr von Freeden remarks, that the whole of the Bernese Oberland might be hidden, "its presence unbetrayed even by an eddy," under the ocean to the north-west of Spitzbergen. Long ago, indeed, Scoresby found no bottom with a two-mile line. Here, then, if anywhere, a ship might expect to find her way, though experience has shown again and again that that way is full of dangers.

Either along this course or along the track suggested by Herr von Freeden, the Pole, I doubt not, will yet be reached. It will be remembered that Sir Edward Parry, setting forth from Spitzbergen on his famous "boat and sledge" expedition, was foiled by an unforeseen difficulty. The whole mass of ice over which he had tracked his way for more than a hundred miles began to drift southward, so that, as fast as Parry and his party travelled northwards, they were set back by the relentless sea and wind. Now, Parry's defeat shows at once the hopefulness of the course suggested above, and of Von Freeden's proposition that an expedition like Parry's should be commenced earlier in the season, when the ice is as yet unbroken. The very fact that Parry's great ice-ship floated freely shows how wide and deep the seas must be even far to the north of the spot he reached. For not only could he see no sign of water in front—and the Arctic voyager can recognise a "water-sky" at a great distance—*but the point where he turned must have been a few days before some hundred miles at least further north*, for he and his party had been floated back more than a hundred miles. There must then have been, that year at least, a course round the floating ice-fields which would have carried a daring seaman to an open sea between the North Pole and station 1, and far to the north of the latter point. On the other hand, the ease with which Parry's party pursued their way northwards shows, as Herr von Freeden justly remarks, that it would be no very difficult matter to attain the Pole itself over the ice, if the journey were made in early summer.

RICHARD A. PROCTOR

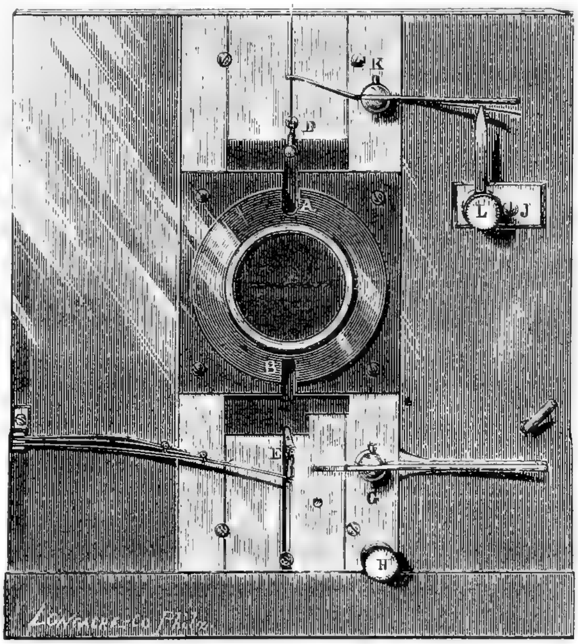
* Petermann's Geog. Mittheilungen, Part VI. The paper on "the scientific results of the first German North-polar Expedition," by Herr W. von Freeden, in this number of the Mittheilungen, will well repay careful study. In Part IX. the progress and results of this year's expedition, so far as they are yet known, are detailed in a series of letters from the people on board the *Germania*.

IMPROVED ECLIPSE CAMERA

IT is to be hoped that shortly, in view of the approaching total eclipse in December next—to observe which we trust a Government expedition will be organised—English astronomers will be making arrangements for obtaining as valuable a series of photographs as the one which rewarded the efforts of the American astronomers last year.

We therefore append a description of the important modifications successfully introduced by Professor Morton, of Philadelphia.

A B represents the face plate of the camera, to which the eye-piece tube was attached, its other end being screwed to the telescope. The diaphragm plate, D E, moved across the axis of the instrument, being drawn downwards by the combined spring, C F. The strength



of this spring could be reduced by raising the outer end of one or both the upper strips so as to disengage the forks at their end from the lower spring, and then turning them forward in a direction normal to the front of the box, out of the way.

The spring was attached to the diaphragm plate by a swivel hook.

A number of diaphragm plates were provided, with slits respectively of $\frac{1}{40}$, $\frac{1}{30}$, $\frac{1}{20}$ and $\frac{1}{10}$ of an inch in width. These plates could be readily interchanged, and, in combination with the springs, gave a very wide and yet delicate series of fixed adjustments for the times of exposure.

To make the exposure, the plate was drawn up until the projecting pin, D, could be caught on the lever, K, which would then retain it. On depressing the outer end of this lever, however, with the finger, the hold on the pin was disengaged, and the plate flashed across the axis of the tube, allowing light to traverse the narrow slit as it flew past. The plate was then arrested on the end of the second lever, G. When an exposure of some seconds was required, as during the totality, a plate having a round orifice exposing the entire field of the eye-piece was substituted for the one with the narrow slit, and was so arranged that, when caught by the upper lever, it covered the lens, but when fallen to the second lever, exposed it entirely; when, however, this lever was in turn touched, the plate descended again far enough once more to close the lens. By touching these two levers in succession, it was then possible to make a "time exposure" with great nicety and accuracy, as proved by actual experience during the eclipse.

To secure a chronographic record of each exposure, a binding screw was provided to make one connection with the general mass of the face-plate including lever K, and another at L, to carry on the circuit when the downward motion of the lever brought the spring at its side in contact with the point projecting from L. In raising the lever for a new exposure, the spring at its side was pressed back so as to pass the point without contact.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Kant's View of Space

THE following paragraphs, I believe, faithfully render sundry passages of Kant's writings:—

"Objects are given to us by means of sense (Sinnlichkeit), which is the sole source of intuitions (Anschauungen); but they are thought by the understanding, from which arise conceptions (Begriffe)." ("Kritik," p. 55. Hartenstein's Edition.)

"The understanding is the faculty of thought. Thought is knowledge by means of conception." (*Ibid.* p. 93.)

"The original consciousness of space is an intuition *à priori*, and not a conception (Begriff)." (*Ibid.* p. 60.)

"Space is nothing else than the form of all the phenomena of the external senses; that is, it is the subjective condition of sense, under which alone external intuition is possible for us." (*Ibid.* p. 61.)

"Our nature is such, that intuition can never be otherwise than sensual (Sinnlich); that is, it only contains the modes in which we are affected by objects. On the other hand, the power of thinking the object of sensual intuition, is the understanding. Neither of these faculties is superior to the other. Without sense, no object would be given us, and without understanding none would be thought. Thoughts without contents are empty, intuitions without conceptions (Begriffe) are blind." (*Ibid.* p. 82.)

"Time and space are 'mere forms of sense'" (Formen unserer Sinnlichkeit, "Prolegomena," p. 33) and "mere forms of intuition." ("Kritik," p. 76.)

With these passages before one, there can be no doubt that that thorough and acute student of Kant, Dr. Ingleby, was perfectly right when he said that Kant would have repudiated the affirmation that "space is a form of thought." For in these sentences, and in many others which might be cited, Kant expressly lays down the doctrine that thought is the work of the understanding, intuition of the sense; and that space, like time, is an intuition. The only "forms of thought" in Kant's sense, are the categories.

T. H. HUXLEY

January 14

I DO not believe Professor Sylvester has been betrayed, as Mr. G. H. Lewes asserts, into any misconception of this matter by me.

When Kant, at the outset, says, "Alles Denken aber muss sich, es sei geradezu oder im Umschweife, vermittelst gewisser Merkmale, zuletzt auf Anschauungen...beziehen," it would take the veriest dunderhead not to see that all forms of intuition must be, indirectly at least, forms of thought. I never dreamed of disputing so obvious a position. But I object to the phrase "forms of thought," as designating Space and Time, on the ground of precision. They are *peculiarly* forms of general Sense, and not forms of Thought *as Thought*. Kant, I believe, eschewed the phrase in that sense, and, for all I see, might for the same reason have disclaimed it.

Ilford, Jan. 14

C. M. INGLEBY

IT is not *my* habit "when objections are made to what I have written, silently to correct my error or silently disregard the criticism." If the objections are well founded, I think it due to the cause of truth to make a frank confession of error, and in the opposite case to reply to the objections.

With reference, then, to Mr. Lewes's strictures in NATURE's last number, I beg to say that Dr. Ingleby has "betrayed" me into no error. If I have fallen into error, it is with my eyes open, and after satisfying myself by study of Kant, that to speak of Space and Time, whether as forms of understanding, or as forms of thought, is an unauthorised and misleading mode of expression. Space and Time are forms of sensitivity or intuition. The categories of Kant (so essentially in this point differing from those of Aristotle) do not contain Space and Time among them, and are properly called forms of understanding or thought.

To the existence of thought the operation of the understanding is a necessary preliminary.

Sensibility and intuition are antecedent to any such operation.

Can Mr. Lewes point to any passage in Kant where Space and Time are designated *forms of thought?* I shall indeed be surprised if he can do so—as much surprised as if Mr. Todhunter or Mr. Routh, in their Mechanical Treatises, were to treat *energy* and *force* as convertible terms. To such a misuse of the word energy it would be little to the point to urge that *force without energy is a mere potential tendency*. It is just as little to the point in the matter at issue, for Mr. Lewes to inform the readers of NATURE that *intuition without thought is mere sensuous impression*.

Dr. Ingleby has rendered, in my opinion, a very great service to the English reading public, by drawing attention to so serious and prevalent an error as that of confounding the categories (the proper forms of thought *as thought*) with Space and Time, the forms of intuition, the Sentinels, so to say, who keep watch and ward outside the gates of the Understanding.

Athenæum Club, Jan. 15

J. J. SYLVESTER

Correlation of Colour and Music

SOME twenty-six or twenty-seven years ago, in a lecture on Light at the London Institution, I suggested an analogy between the octaves of Sound and Light; not then knowing the view of Sir J. Herschel to which Dr. Pereira subsequently called my attention.

I endeavoured to support the hypothesis of three primary colours by supposing the intermediate colours to arise from the blending of the primary. Thus orange would result from the blending of red and yellow, green from yellow and blue, and violet from the secondary red impinging on the blue or indigo. This seemed to me a less arbitrary explanation than that of Sir D. Brewster of a superposition (in degrees of intensity chosen to suit the hypothesis) of all the primary colours throughout the whole spectrum. Spectrum analysis has now much changed our views on this subject.

The interesting article in your number for January 13, by Mr. Barrett, has recalled my attention to the matter, and induces me to ask whether he, or any of your contributors, can explain a phenomenon which I have very often observed, as have doubtless others, but which I have never seen noticed in any work on Light.

It is this. When a very brilliant solar-rainbow is seen, there is plainly visible within, and forming a continuous spectrum with the main rainbow, a repetition, but in much narrower bands, of the rainbow: the same seven colours in the same order; and within this again, I have, on certain occasions, detected a third. Are these repetitions of the spectrum as suggested by Sir J. Herschel? If so, we should have two, three, and more reds, and so of the other colours, in which light, producing the impression of the same colour on the retina, would have different wave-lengths, say, in the ratios of one, two, four, &c.; or is the phenomenon due to some other cause?

W. R. GROVE

January 15

I VENTURE to call attention to a curious point in connection with the very interesting note by Mr. W. F. Barrett on the "Correlation of Colour and Music," which appeared in yesterday's NATURE (January 13). The researches of Helmholtz and others have (as is well known) overthrown, to a certain extent, the old idea of the three primary colours—red, blue, and yellow—and have shown that if any *three* are to be selected, red, blue, and green have greater claims than the former. Now, in Mr. Barrett's diagram these correspond to the following notes:—

Red.	Yellow.	Green.	Blue-Indigo.
C.	E.	F.	G.
Tonic.	Third.	Sub-dominant.	Dominant.

The old triad, red, yellow, blue, correspond to the common chord; but the new triad, red, green, and blue, to the *tonic, subdominant* (or fourth) and *dominant* (or fifth); or, in other words, to the three notes which constitute in music the *fundamental base* of the scale.

F. DE CHAUMONT, M.D.

Army Medical School, Netley, Jan. 14

Government Aid to Science

I CANNOT but feel flattered that my letter on this subject should have been thought so dangerous as to require a leading article in the same number by way of immediate antidote, but I must beg you to allow me to correct one or two errors into which you have fallen as to the views I really hold, and which it seems I failed clearly to express. You say, you "understand Mr. Wallace to mean that the main result of cultivating science is merely the gratification of those directly engaged in the pursuit, and that they who do not take this personal interest in it derive little or no benefit from it."

The first half of this passage does express, though imperfectly, what I believe to be the truth; the latter half expresses the exact opposite of what I have ever thought or intended to write on the subject. The main result of the cultivation of science I hold to be, undoubtedly, the elevation of those who cultivate it to a higher mental and moral standpoint; while the secondary, but not less certain result, is the acquisition of countless physical, social, and intellectual benefits for the whole human race. But if these are the *secondary* and not the *primary* results of cultivating science, it seems to me to be radically unsound in principle, and sure to fail in practice, if by means of any system of State support we seek to find a short cut to these secondary results.

The only logical foundation for advocating the furtherance of scientific discovery by the expenditure of public money, would be the belief that science can be most successfully pursued by those whose chief object is to make practical and valuable discoveries; whereas the whole history of the progress of science seems to me to show that the exact opposite is the case, and that it is only those who in a noble spirit of self-sacrifice give up their time, their means, even their lives, in the eager and loving search after the hidden secrets of Nature, who are rewarded by those great discoveries from which spring a rich harvest of useful applications.

One more point: I do not admit that it is just to tax the community for all the Government institutions you name, but in the short space at my command I could not go into details. I have stated how I think some of these institutions require modification to make them accord with the fundamental principle of just government; and if that principle is a sound one, it is easy to see in what way the others should be dealt with. As an example I may indicate, that a detailed survey, like that of the large-scale Ordnance-maps, being primarily a boon to the landowners of the country, should not be *wholly* paid for by the public.

ALFRED R. WALLACE

Food of Oceanic Animals

I FIND on my return home that Dr. Wallich is vexed at my not having given him the credit of having already answered the question which I ventured to put in the ninth number of NATURE, and that he apparently accuses me of inconsistency as regards my estimate of his observations on deep-sea life. I hasten to assure him that my opinion in that respect has never changed; nor do the extracts which he has given from my reports warrant such an inference.

I certainly overlooked some of his remarks in the "North Atlantic Sea-bed" bearing on my question, in which he says (page 131), it may be asked "under what other conditions than exceptional ones can marine animal life be maintained without the previous manifestation of vegetable life, as must be the case if it exists at extreme depths?" And he answers this inquiry by submitting that "in the majority of the marine Protozoa—as for instance in the Foraminifera, Polycystina, Acanthometræ, Thalassicollidæ, and Spongidæ—the proof of these organisms being endowed with a power to convert inorganic elements for their own nutrition, rests on the indisputable power which they possess of separating carbonate of lime or silica from waters holding these substances in solution." But this does not appear to be a satisfactory answer to the inquiry; because a limpet separates carbonate of lime from sea-water in order to construct its shell, yet it cannot be assumed that this animal (which is well known to be a vegetable-eater) has also the power of converting other inorganic substances for its own nutrition. Among the Protozoa, many, probably all, of the Rhizopods are animal-eaters. With regard to sponges, Dr. Bowerbank says (Mon. I., p. 122) that in the greater number their nutriment "is probably molecules of both animal and vegetable bodies, either living or derived from decomposition," and that "the fæcal matters exhibit all the characteristics of having undergone a complete digestion."

J. GWYN JEFFREYS

P.S.—In the 10th number of NATURE, Dr. Martin Duncan, under the head of "Deep-Sea Corals," opposes a statement in what he calls a postscript to my report on the "Deep-Sea Dredging Expedition in H.M.S. *Porcupine*." This statement was not part of my report, nor had I anything to do with it.

J. G. J.

MY attention has been directed to a paragraph in one of the late numbers of NATURE referring to Professor Dickie's interesting remarks on the bathymetrical distribution of Algæ, and raising the question of the mode of nutrition of the great sheet of animal life, which is now shown to extend over the bottom of the sea at all depths.

This curious problem was of course one of the first which engaged our interest when working up the results of the dredging cruise of the *Lightning*. In April last, I proposed a solution in one of the "Afternoon Scientific Lectures" in connection with the Royal Dublin Society, which was afterwards reprinted in full in the "Annals and Magazine of Natural History." I see from notices in several newspapers that this question has excited considerable interest; I may, perhaps, therefore be allowed to quote the passage in the lecture specially bearing upon it:—

"The question of the mode of nutrition of animals at these great depths is a very singular one. The practical distinction between plants and animals is, that plants prepare the food of animals by decomposing certain inorganic substances which animals cannot use as food, and recombining their elements into organic compounds upon which animals can feed. This process is, however, constantly effected under the influence of light. There is little or no light in the depths, and naturally there are no plants: but the bottom of the sea is a mass of animal life. On what do these animals feed? The answer seems to be sufficiently simple: nearly all the animals—practically *all* the animals, for the small number of higher forms feed upon these—belong to one sub-kingdom, the Protozoa, whose distinctive character is that they have no special organs of nutrition, but that they absorb nourishment through the whole surface of their jelly-like bodies. Most of these animals secrete exquisitely-formed skeletons, sometimes of lime, sometimes of silica. There is no doubt that they extract both of these substances from the sea-water, although silica often exists there in quantities so small as to elude detection by chemical tests. All sea-water contains a certain proportion of organic matter in solution. Its sources are obvious. All rivers contain a large quantity: every shore is surrounded by a fringe which averages about a mile in width of olive and red sea-weeds: in the middle of the Atlantic there is a marine meadow, the Sargasso Sea, extending over three millions of square miles: the sea is full of animals which are constantly dying and decaying; and the water of the Gulf Stream, especially, courses round coasts where the supply of organic matter is enormous. It is, therefore, quite intelligible that a world of animals should live in these dark abysses, but it is a necessary condition that they should chiefly belong to a class capable of being supported by absorption, through the surface, of matter in solution; developing but little heat, and incurring a very small amount of waste by any manifestation of vital activity. According to this view, it seems highly probable that at all periods of the earth's history, some form of the Protozoa, rhizopods, sponges, or both, predominated greatly over all other forms of animal life in the depths of the warmer regions of the sea; whether spreading, compact, and reef-like, as the Laurentian and Palæozoic eozoön;

or in the form of myriads of separate organisms, as the globigerinæ and ventriculites of the chalk. The rhizopods, like the corals of a shallower zone, form huge accumulations of carbonate of lime, and it is probably to their agency that we must refer most of those great bands of limestone which have resisted time and change, and which come in here and there with their rich imbedded lettering, to mark, like milestones, the progress of the passing ages."

The following passage, referring to another aspect of the question, was published in the 114th Number of the "Proceedings of the Royal Society":—

"The vitreous sponges along with the living Rhizopods and other Protozoa which enter largely into the composition of the upper layer of the chalk-mud, appear to be nourished by the absorption through the external surface of their bodies of the assimilable organic matter which exists in appreciable quantity in all sea-water, and which is derived from the life and death of marine animals and plants, and, in large quantity, from the water of tropical rivers. One principal function of this vast sheet of the lowest type of animal life, which probably extends over the whole of the warmer regions of the sea, may possibly be to diminish the loss of organic matter by gradual decomposition, and to aid in maintaining in the ocean the 'balance of organic nature.'"

I cannot at present enter into detail, as the whole subject of the conditions of life at great depths will be fully discussed in the second part of the preliminary report to the Royal Society on the *Porcupine* Expedition. I may mention, however, that the much more extended researches of the past summer have increased our confidence in the general accuracy of our former conclusions; while careful analyses by the physicists who accompanied the expedition have proved the existence in the water at all depths of a very appreciable and tolerably constant proportion of organic matter in a condition suitable for assimilation by animal organisms. WYVILLE THOMSON

January 7

MY friend Mr. J. Gwyn Jeffreys informs me that he is not answerable for the postscript to his letter, a sentence in which I noticed in a letter published by you in the last number of NATURE. Will you kindly insert this statement.

Lee, January 10 P. MARTIN DUNCAN

[The postscript was editorial, and so appears on the face of it.]

NOTES

IT was announced by Mr. Lockyer at the meeting of the Royal Astronomical Society, on Friday last, that the great refractor of 25 inches aperture, constructed by the Messrs. Cooke, of York, is so near completion that it will be erected in the observatory prepared for it at Gateshead early next month. The completion of this magnificent instrument, with which Mr. Newall has endowed science, marks an epoch in astronomy. Mr. Newall has in fact done what the French Government has already done, and what our Government ought to have done; he has furnished observers with an instrument capable of grappling with the physical problems which have now to be solved—one on a level with our present requirements; and we doubt not that when it is once at work, the wish of its owner, that science may be advanced by it, will be amply fulfilled.

WE are informed that the Senate of London University have proposed to establish a Faculty of Science.

THE last number of the journal of the German Chemical Society contains a biographical sketch of the late Professor Graham, in which his scientific merits are more fully analysed than in the interesting sketch lately published by Professor Williamson in the columns of NATURE. Professor Hofmann, the author of the German biographical notice, has added a photograph of the late Master of the Mint, and an autographic copy of a letter of particular interest to the society. It runs as follows:

"4, Gordon Square, London, Dec. 28, 1868. My dear Hofmann,—I am much gratified by the receipt of your kind letter, and have since received the official intimation of my election as an honorary member of the Berlin Chemical Society over which you preside, which I esteem a high compliment and great honour. I have written a line to Messieurs the secretaries in acknowledgment, which I beg you to forward to them. There is a communication of mine before the Royal Society at present, which I believe will amuse you, or at least the hardiesse of the thing will surprise. What do you think of Hydrogenium, a white magnetic metal of the specific gravity 2?—I remain, dear Hofmann, sincerely yours, THOS. GRAHAM."—On Saturday, January 8, this society gave a dinner to Professor Hofmann, on his retiring from the presidency. The presence of a great number of the celebrities of the town added to the significance of this meeting. Professor Magnus (who acted as chairman on the occasion), Dove, Virchow, Rose, Dubois-Raymond, Kronecker, Curtius, and others, as also some of the Ministers of State, the American Ambassador (Mr. Bancroft), &c., honoured the meeting with their presence, and partly with their speeches. A great number of the foreign members sent messages from England and France, or from distant parts of Germany. The following telegram was received from M. Dumas, at Paris:—"Félicitations et vœux! Longue prospérité à la société! Longue vie à Hofmann! Votre fête est la fête de famille des chimistes du monde entier, qui tous l'admirent et l'aiment." A photolithograph representing Dr. Hofmann, the discoverer of compound Ammonium, as Jupiter Ammon, surrounded by a halo of Aniline colours, was distributed and explained by the artist, and a hymn to Aniline, composed for the occasion, gave a humorous tone to the latter part of the festival.

ALL readers of the "Origin of Species" are aware that the theory now universally (and rightly) known as "Darwinian," was independently conceived and thought out by a naturalist who knew nothing of Darwin's views of the operation of natural selection, and who was at that time thousands of miles away from England. The English public are therefore not likely to forget that to Mr. Alfred Wallace, as well as to Mr. Darwin, belongs the distinction of having discovered "a new idea, a new genus of thought." In Germany, where Darwinism has excited such profound interest, the claims of Mr. Wallace have been somewhat overlooked by the distinguished men who have expounded the theory of natural selection. This has now been rectified by the publication of a pamphlet entitled "Charles Darwin und Alfred Russell Wallace," in which Dr. A. B. Meyer reprints the papers by which the theory was first made known; narrates the circumstances of their publication; and gives slight sketches of the lives of their authors. Dr. Meyer adds to these biographical sketches, lists of the writings of their subjects. Such lists are sometimes not brought down to so late a date as they should be; but in the case of Mr. Wallace, so far is this from being the case, that we see noted as published in the pages of NATURE an article on Geologic Time, which we regret to say we have not yet been able to lay before our readers, owing to the extraordinary pressure upon our columns.

PROFESSOR MAYER was elected, at the meeting of the French Academy on January 10, a correspondent of the section of Physics in place of the late Prof. Matteucci. Of 47 votes, Prof. Mayer received 40; of the remainder, 5 were given to Prof. Kirchhoff, and 1 each to M. Ångström and Sir W. Thomson. We are indebted to the *Revue des Cours Scientifiques* for the following information with regard to vacancies in the lists of corresponding members of the various sections of the Paris Academy of Sciences. The Astronomical section has four corresponding members to replace, namely, Enke, Admiral Smyth, Petit, and Valz; but as the most recent vacancy occurred so long ago as 1867, it is probable that the section considers that the number of places for corresponding members exceeds that of the foreign and provincial astronomers worthy of the honour. In the Physical section, into which, as our readers are aware, Prof. Helmholtz of

Heidelberg and Dr. Mayer of Heilbronn, have recently been elected, there is still a vacancy caused by the death of Principal Forbes, which took place in December 1868. In the section for Geography and Navigation no successor has yet been appointed to M. A. d'Abbadie, elected *membre titulaire* in April 1867. In the Chemical section there are two vacancies, that of Bérard of Montpellier, who died in June last, and that of Prof. Graham, the Master of the Mint, who died in September. There are likewise two vacancies in the Mineralogical section, which includes the Geologists and Palæontologists. They were occasioned by the promotion of Sir Roderick Murchison to the rank of Foreign Associate, and the death of M. Fournet of Lyons. M. Harrman has been nominated by this section for the first place; Dr. W. H. Miller of Cambridge will probably obtain the second. Mr. Dana is, however, also spoken of; likewise two French geologists, M. Lory of Grenoble and M. Leymerie of Toulouse. The Zoological and Anatomical section has three *fauteuils* to dispose of, those of Quoy of Brest, Carus of Dresden, and Purkinje of Prague. One of them will in all probability be assigned to Prof. Huxley. Lastly, there are two vacancies in the Medical section, those of Panizza of Pavia and Sir W. Lawrence. Prof. Lebert of Breslau will almost certainly be nominated by the section for one of the vacancies.

THE Chancellor of the North-German Confederation has presented to the Federal Council the report of the Scientific Commission on the best means of observing the transit of Venus in 1874. The detailed report proposes to send two expeditions to different points of the northern, and two others to different localities in the southern hemisphere.

THE third volume of Dr. Percy's admirable "Metallurgy" will shortly be issued. There will still be another volume to complete the work.

THE Royal Irish Academy at their last meeting approved of some alterations in the bye-laws proposed by the Council. By these alterations the Council for the future will be divided into two Committees: one of Science, consisting of eleven members, and one of Polite Literature and Antiquities, consisting of ten members. The Committee of Publication to consist of four members from each of the Committees of Council. This change will very much simplify the management of the Academy. The first election under the new bye-laws will take place on the 16th March next, and we trust that at least one biologist may be elected into the Committee of Science. For many years past neither a zoologist nor a botanist has been elected into the Council.

L'Institut has announced that from the beginning of the new year it will open its columns to the discussion of scientific subjects of interest to the public at large. We hold that it is an important part of the work of a weekly scientific journal to afford opportunity for instructing others than scientific workers, and also to afford opportunity for a more careful and thorough sifting of most scientific questions than is possible at the meetings of learned societies or in the pages of periodicals published monthly or quarterly. It is satisfactory to us to find that our views on this head are endorsed by so long established and ably conducted a journal as *L'Institut*. As the space which we can devote to letters is necessarily limited, we take this opportunity of begging that our correspondents will make their communications as short as is consistent with clearness.

IN a paper published in a recent number of the *Journal of the Society of Arts*, Mr. Alexander Wallace expresses his conviction that the cultivation of the silkworm may now be successfully and profitably carried out in England, as the causes which led to the failure of the attempts made by the British, Irish, and Colonial Silk Company some forty years ago have been greatly modified. He advocates the adoption of the oak-feeding silkworm of Japan, Bombex Yama-mai, and thinks that the experience of a few more seasons will show the limits of temperature and locality wherein it may be acclimatised.

HAVING adverted in our number of last week to the view recently maintained by Prof. Huxley that the difference between Celt and Saxon is merely one of language, we think it right to call attention to the rejoinder of a "Devonshire Man," printed in the *Pall Mall Gazette* of Tuesday last. The writer energetically opposes Prof. Huxley's attempt to prove identity of race between the natives of Tipperary and the men of Devonshire. He shows further, that Cæsar was fully alive to the essential difference of character between the Celts and the Teutons, and that he defined those characters in language which for accuracy and precision could not be exceeded in our day. The "Devonshire Man" did not, however, adduce any evidence depending on physical characters in support of his view of the question; probably leaving this powerful weapon to some one who has made a special study of European ethnography.

MR. W. CHANDLER ROBERTS has been appointed Chemist to the Mint. The selection of this gentleman to fill this important office is a good one: many points arise during the working of the precious metals that require careful investigation, and Mr. Roberts will doubtless also continue the valuable researches interrupted by the death of Professor Graham.

WE have received specimens of a new process of photo-mechanical printing, patented by Messrs. Edwards and Kidd, of 22, Henrietta Street, Covent Garden. It seems admirably adapted for the reproduction of the works of the great masters of etching and engraving. We are unable as yet to speak of the process as applied to photographs of landscapes.

THE Royal Danish Society of Sciences has offered the following prizes for scientific memoirs, which may be written in Latin, French, English, German, Swedish, or Danish, and must be sent to the secretary of the Society, Professor J. S. Steenstrup, before the end of the month of October next. A gold medal for a memoir establishing a mathematical theory of some branch of assurance hitherto destitute of any such foundation; a gold medal for an experimental and theoretical essay on the law of Cauchy relating to the dispersion of coloured rays, with especial reference to the number of constants necessary to be introduced into the formula; and the Classen prize of 300 rixd. (about 34*l.*), for an investigation of the movement of the air in a system of ventilation. Full details of the questions, in French, will be found in the "Oversigt" of the Society for 1869, No. 1.

MR. JAMRACH, of St. George's Street East, in a letter addressed to *Land and Water*, gives the following extraordinary list of animals now on sale at his establishment:—"1 pair of South African lions, 1 brown hyena, 1 striped hyena, 8 Tasmanian devils, 1 large rare dasyurus, 8 dasyurus maugeii, 6 ichneumons, 4 banded ichneumons, 1 musk cat, 1 African skunk, 1 pair American black bears, 1 pair zebras, 1 pair imported yaks, 6 llamas, 2 Iceland ponies, a new deer, a Brocket deer, a springboc, a harnessed antelope, 2 female and 1 male Wapiti deer, a female nylghaie, a pair fat-tailed sheep, 10 kangaroos, 1 broad-nosed wombat, 1 pair mouflon, a Formosa pig, 8 large crested porcupines, 4 Java porcupines, 1 Java hare, 4 vulpine phalangers, 2 black phalangers, 1 pacca, 4 baboons, 1 pair large drills, 1 mandrill, 2 Mona monkeys, 1 ringtail monkey, 3 green monkeys, 1 blue fox, 1 pair flying opossums, 1 pair emus, a maraboo, a pair Mexican cranes, a pair Demoiselle cranes, 5 spur-wing geese, 16 pair Carolina ducks, 1 pair Australian wild ducks, 2 pair white peafowl, 1 pair lineated pheasants, sand grouse, Mogadore partridges, a New Zealand rail, large European vulture, 1 black hawk, 1 condor, a female Bateleur eagle, a secretary, 2 caracaras, 1 Australian thick-knee, 1 snapping turtle, 20 grey parrots, 12 green parrots, 20 king lories, 1 China lori, 4 Pennant's parakeets, 3 Roselle's parakeets, 12 large cockatoos, 16 rose cockatels, 5 Leadbeater's cockatoos, 3 Nasicu cockatoos, 1 China cockatoo, 10 pair cockatilles, 4 large white-crested cockatoos, 1 male bloodwing, 1 mealy rosella, 6 ringnecked parakeets, 2 Alexandrine parakeets, 1 dwarf parrot, 2 rare Amazones, 7 pair Carolina parrots, piping crow, 1 mynah, 60 pair African love-birds, 80 nonpareils, 1 hang nest, 1 Indian crow pheasant, 55 pairs St. Helena wax-bills, 60 Virginian nightingales, 20 grey cardinals, 16 popebirds, 20 pair Java sparrows, Wydah birds (yellow-backed, red-shouldered, Cape of Good Hope), Madagascar grosbeaks, zebra waxbills, chesnut finches, Napoleon bishops, common bishops, harlequin doves, zebra doves, Australian doves, necklace doves, 3 blue Australian porphyrios."

We notice that an individual was examined on Tuesday at Worship Street on the charge of sweating sovereigns. The details of the case, which are of considerable importance to the public, will be watched with interest. It appears that the coins are dissolved by acid, aided by a battery, and that the loss in some cases equals about two shillings in the sovereign.

In the track of vessels from Australia to China lies an island called Pleasant Island. Previous to 1865, the natives had a bad reputation. A Captain Brown reported favourably of them in that year, and mentioned that he was told that an Englishman was residing there. In August 1868, Captain Hall, of the barque *Glenisle*, was boarded by the island canoes, and two whaleboats, with two Englishmen, one of whom had been twenty-eight years on the island, and had a son eighteen years of age. They told him they tried to visit all ships passing within easy distance, and seemed anxious for it to be known that they could supply ships with pigs and cocoa-nut oil. By his advice they purposed to cultivate potatoes, and gave him *an advertisement* to put in the colonial papers. Unfortunately, this document has baffled all attempts to decipher it, from the faulty writing. The island was stated by them to be nine miles across, and twenty two miles in circumference.

ANTHROPOLOGY AND ETHNOLOGY

[We have been favoured by the Count Marshal of Austria with the following abstracts of the more important papers read at the Innspruck Congress.]

Prof. Semper on the Natives of the Pellew Islands

These natives have come to a comparatively rather high degree of civilisation, and have been wronged by being ranked among the primitive savages. Prof. Semper, who has lived several months among them, proves his assertion by a detailed exposition of their political, social, and religious institutions. The residence of the pontiff-king and the house where the chieftains of tribes hold their meetings, are decorated with painted basso-relievos. The traces of a commixture of the natives with the Malayan race are insignificant; they seem, however, to have mixed notably with the Papuans.

Prof. Strobel on the Paraderos of Patagonia

These "Paraderos" (from the Spanish verb *parar*, to stay) are accumulations of remnants of repasts, fragments of pottery, unpolished stone-knives, arrow-heads, &c., superficially covered with blown sand. In one of these accumulations a human skeleton, and several skulls of brachy-hypocephalous type, were found. The pottery had evidently been shaped by hand, and burnt hard by an open fire—not in furnaces. The distinction between a Palæolithic and a Neolithic period cannot be maintained with respect to the southern-most portion of South America; no polished stone-implements having hitherto been found south of St. Luis in the centre of the Pampas, although grinding-stones and polishable minerals are not wanting there. The polished stone-implements found at St. Luis may have been imported from Peru. The objects found in the Paraderos must be anterior to the European invasion; neither the Patagonians nor the Indians of the Pampas using at present any stone-weapons, but being armed with lassoes, bolas, and lances. Arrows and bows having gone out of use since the introduction of horses by the Europeans. The Indians of Chaco and the inhabitants of Terra del Fuego, who have refused to use horses, still use arrows as a weapon. Horsemanship seems not to have had any diminishing action on the size of the Patagonians, still conspicuous for tallness; the inhabitants of Terra del Fuego, though no horsemen, being rather of small size. Prof. C. Vogt said that the collections made in South America by Mr. Claray have safely arrived in Europe, and that among them is a human lower jaw of uncommon size. Prof. Seligmann observed that the skeleton of a giant, in the museum of Innsbruck, offers likewise an uncommonly developed lower jaw, a peculiarity mentioned by Prof. Langer as generally connected with gigantic size. Prof. Virchow remarked that the outline of the jaw in question is rather curved than angular.

Prof. Virchow on Comparative Measurements of Crania

It is uncertain whether the great number of crania found in Denmark in sepultures of the Stone Period, belonged to the persons of rank, or to those immolated to honour them—as Mr. Worsaae concludes from the circumstances under which they have been found. At all events, they must have belonged to inhabitants of the Danish isles, or of their immediate neighbourhood. Ninety-six crania have been extracted from one single sepulture near Borreby. Those from the first part of the Bronze Period, when the dead were buried unburnt, are not abundant. Eschricht and Nilsson agree in ascribing the crania of the Stone Period to Laplanders or Esquimaux. The crania of the Greenlanders are conspicuously Dolichocephalous, not to say Scaphocephalous. The insertions of the temporal muscles are unusually distinct, the temporal ridges reaching beyond the *tubera parietalia*; the root of the nose is very narrow and the eyes very near to each other; the facial portion is more developed than in any other race. The few Dolichocephalous crania found in the sepultures are far from offering any analogy to those of Greenlanders. The Laplanders are known to be a Brachycephalous race, whose outward form is evidently the result of their mode of living. The temporal diameter of the crania of this people is ordinarily very considerable, the root of the nose is very broad, and the middle of the lower jaw conspicuously compressed. The crania from the sepultures do not bear more than a distant resemblance to the type just described. The crania of the Finnic race—abstraction made of individual variations—are relatively Brachy-hypocephalous. The Danish crania here in question may be possibly of Finnic origin, the more, as history proves this race to have spread formerly far more southward in Scandinavia than at present. Two forms may be distinguished among these crania, not so discrepant, however, as to indicate the co-existence of two distinct nations, although a commixture between two nations may have taken place. The Slavonians are nearly generally admitted to be Brachycephalous, and the Germans to be Dolichocephalous; the Poles and the Wends, however, make an exception to this rule, being anything but Brachycephalous. Crania from peat-bogs of North Germany exhibited to the Anthropological Congress, held at Paris in 1867, are decidedly Dolichocephalous, not Prognathous, without a decidedly ferocious expression, &c. Those extracted from the Danish peat-bogs exactly resemble them, and have, moreover, the greatest analogy with the crania of the Basques, a nation which (as may be historically ascertained) had spread in ancient times over Southern France and North Italy under the denomination of "Iberians." It results from all this, with some degree of probability, that the nation to which the skulls in the peat-bogs are to be referred was rather of Meridional than of Septentrional origin. Chronological dates, relating to the crania here in question, are still insufficient. At present, no trace of man's existence during the reindeer-period has been ascertained in North Germany. Remains of reindeer have been found in Mecklenburg and lately (probably) in the Uckermark, but not associated with any products of human industry. The co-existence of the Dolichocephali, whose remains have been found in peat-bogs, with the reindeer, is therefore not yet proved, although in some degree probable.

Prof. Seligmann on Exostoses in the Meatus auditorius of Peruvian Crania

SOME years ago Prof. Seligmann found on Peruvian crania of the Titicaca form (cylindrical, elongated by bandages) considerable exostoses on the external meatus auditorius, a very rare morbid affection. No traces of such exostoses were found on the other variety of Peruvian crania so nearly related to the North American form, and, like these, flattened by pressure between boards. The crania first referred to are most similar to the so-called *Avarian* skulls, to be met with from Austria as far as into France; but exostoses have never been found on any of these last. The cause of these exostoses was at last found out in the narrative of the conquest of Peru by coeval Spanish authors, all describing the solemn inauguration of the descendants of the Incas, who had come to the age of sixteen years. They were then compelled to undergo most exciting exertions of body and mind, and the hardest privations; the ceremony of piercing the ears being the term of these severe trials. The lobes of both ears were widened by introduction of metallic cylinders, so that a gold or silver disc of the diameter of an orange could find room in each of them. The Spaniards designated the wearers of this distinction as "Orejones" (Great-ears). A Spanish author says, it would scarcely be credible that the lobes of the ear could bear such a weighty ornament if they were not sustained by a loop of a finger's size. The excitement attending the trials, the comparatively late epoch of the operation, together with its rapid and violent mode of performance, may possibly have provoked a pathological process affecting the cartilaginous, and, subsequently, the osseous portion of the ears. Many tribes lengthen the lobes of their ears by introducing pieces of wood, &c., and a South American tribe is named "Orejones" on account of this custom; in these cases, however, the lengthened portion is relaxed. If the above supposition is exact, it leads to the following result: all the Peruvian crania of the Titicaca form, offering the above-described exostoses, are those of male individuals of high caste, having passed their sixteenth year; and the appellation "Inca crania," hitherto applied to flattened Peruvian skulls, is inexact. Deafness was not the necessary consequence of these exostoses, the narrowest aperture of the meatus auditorius being sufficient for the perception of sounds.

Dr. Glatter on the Influence of Race-differences on the Vital Processes

THIS influence is evident in the descendants of an Italian colony, living at Lemberg, who are in the habit of entrusting themselves for treatment to native Italian physicians, who, according to their custom, treat their patients with frequent bleedings, to the amount of 8 to 10 ounces, without any damage to their health. Poles, submitted to the same treatment, often suffer very bad consequences from it. The natives of Alpine regions established at Vienna are endowed with a high degree of vitality, and generally of longevity. The Servians are very prolific in their native country; north of Mohacs, however, the number of births among them is diminishing, so that the population of Servian places approaches extinction. Births are numerous and easy, and deaths comparatively few among Jews in every country, thus proving their strong accommodative power, and consequently their aptitude for commercial business. At Pesth, Jewish merchants reach a higher average age than Christian ones; the reverse is the case there among workmen, as tailors, &c. Suicide is rare, mental alienation frequent among Jews. Among Magyars, the number of births is moderate, the mortality rather great, and as a necessary consequence, the Slavonian population is more and more encroaching on them. Notwithstanding the very notable introduction of Turkish blood during the long occupation in the sixteenth and seventeenth century, the Finnic race and characters have suffered but little alteration, as proved by the striking similitude between Magyar and Finnic crania. The Hungarian Slovacks possess a high degree of vitality, and, notwithstanding certain noxious customs (hot wine given to women immediately after parturition, and brandy given to sucking babes), the mortality among them is anything but considerable. The Wends, living in groups in the Comitate of Wieselburg, are tall, with small heads, and, notwithstanding their irregular and excessive mode of living, generally attain to a good old age. The Germans in the Comitate of Pesth are all very prolific, but their number increases but moderately, as the rate of mortality is rather considerable. The Roumanians are reported to be generally of small size, with rather light brain, and to be subject to tuberculosis and to caries of the teeth. The Poles are more affected by epidemics than the Ruthenians; deaths among them are more numerous than births, while the Ruthenian population is constantly increasing in numbers. Prof. Sigmund has observed in the case of Italians and Spaniards, that wounds are more inclined to gangrene than in individuals of other races.

Prof. C. Vogt on a Microcephalous Subject

THE data concerning this subject have been communicated by M. de Vilanova, Professor of Geology at Madrid. His name is Vincenzo Ortis, of Codina, born at Castillon del Duca (province of Valencia), in 1813. The dimensions of his head are: facial angle, 59°; circumference of the cranium, 0·46 metres; upper arch, 0·19 m.; longitudinal diameter, 0·14 m.; transverse diameter, 12 m. His total length does not exceed 1 metre. The sternal limbs are very long, with a rudimentary sixth finger on each hand; the abdominal members are short, with a sixth toe on each foot; his whole body is covered with long hairs. His character is rather meek and timid; when irritated he tears his clothes without doing harm to others. He is unable to speak, but makes very expressive faces. His mode of progression is by leaps. The comparatively advanced age of fifty-six years, and the existence of six fingers and toes, make Ortis an exception among Microcephalous subjects.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 13.—The following papers were read:—"On the Mineral Constituents of Meteorites," by Nevil Story-Maskelyne, M.A., Professor of Mineralogy in the University of Oxford, and Keeper of the Mineral Department, British Museum. Communicated by Prof. H. J. Stephen Smith, F.R.S. [We are compelled to postpone an abstract of this paper.]

"On Fluoride of Silver." Part I. By George Gore, F.R.S. This communication treats of the formation, preparation, analysis, composition, common physical properties, and chemical behaviour of fluoride of silver. The salt was prepared by treating pure silver carbonate with an excess of pure aqueous hydrofluoric acid in a platinum dish, and evaporating to dryness, with certain precautions. The salt thus obtained invariably contains a small amount of free metallic silver, and generally also traces of water and of hydrofluoric acid, unless special precautions mentioned are observed. It was analysed by various methods: the best method of determining the amount of fluorine in it consisted in evaporating to dryness a mixture of a known weight of the salt dissolved in water, with a slight excess of pure and perfectly caustic lime in a platinum bottle, and gently igniting the residue at an incipient red heat until it ceased to lose weight. By taking proper care, the results obtained are accurate. The reaction in this method of analysis takes place according to the following equation: $2AgF + CaO = CaF_2 + 2Ag + O$. Sixteen parts of oxygen expelled equal thirty-eight parts of fluorine present. One of the methods employed for determining the amount of silver consisted in passing dry ammonia over the salt in a platinum boat and tube at a low red heat. The results obtained in the various analyses establish the fact that pure fluoride of silver consists of nineteen parts of fluorine and 108 of silver. Argentic fluoride is usually in the form of yellowish brown earthy fragments; but when rendered perfectly anhydrous by fusion, it is a black horny mass, with a superficial satin lustre, due to particles of free silver. It is extremely deliquescent and soluble in water; one part of the salt dissolves in ·55 part by weight of water at 15°·5 C.; it evolves heat in dissolving, and forms a strongly alkaline solution. It is nearly insoluble in absolute alcohol. The specific gravity of the earthy-brown salt is 5·852 at 15° 5 C.; the specific gravity of its aqueous solution, at 15°·5 C., saturated at that temperature, is 2·61. By chilling the saturated solution, it exhibited the phenomenon of supersaturation and suddenly solidified, with evolution of heat, on immersing a platinum plate in it. The solution is capable of being crystallised, and yields crystals of a hydrated salt; the act of crystallisation is attended by the singular phenomenon of the remainder of the salt separating in the anhydrous and apparently non-crystalline state, the hydrated salt taking to itself the whole of the water. The fused salt, after slow and undisturbed cooling, exhibits crystalline markings upon its surface. The dry salt is not decomposed by sunlight; it melts below a visible red heat, and forms a highly lustrous, mobile, and jet-black liquid. It is not decomposed by a red heat alone; but in the state of semi-fusion or of complete fusion it is rapidly decomposed by the moisture of the air with separation of metallic silver; dry air does not decompose it. In the fused state it slightly corrodes vessels of platinum, and much more freely those of silver. The salt in a state of fusion with platinum electrodes conducts electricity very freely, apparently with the facility of a metal, and without visible evolution of gas or corrosion of the anode; a silver anode was rapidly dissolved by it, and one of lignum-vitæ charcoal was gradually corroded. A saturated aqueous solution of the salt conducted freely with electrolysis, crystals of silver being deposited upon the cathode, and a black crust of peroxide of silver upon the anode; no gas was evolved; with *dilute* solutions gas was evolved from the anode. By electrolysis of anhydrous hydrofluoric acid with silver electrodes, the anode was rapidly corroded. The electrical order of substances in the fused salt was as follows, the first-named being the most positive: silver, platinum, charcoal of lignum-vitæ, palladium, gold. In a dilute aqueous solution of the salt, the order found was: aluminium, magnesium, silicon, iridium, rhodium, and carbon of lignum-vitæ, platinum, silver, palladium, tellurium, gold. The chemical behaviour of the salt was also investigated. In many cases considerable destruction of the platinum vessels occurred, either in the experiments themselves, or in the processes of cleaning the vessels from the products of the reactions. Hydrogen does not decompose the dry salt, even with the aid of sun-light, nor does a stream of that gas decompose an aqueous solution of the salt, but the dry salt is rapidly and perfectly decomposed by that gas at an incipient red heat, its metal being liberated. Nitrogen has no chemical effect upon the salt, even at a red heat, nor upon its aqueous solution. Dry ammonia gas is copiously absorbed by the dry salt. In one experiment the salt absorbed about 844 times its volume of the gas. The salt in a fused state is rapidly and perfectly decomposed by dry ammonia gas, and its silver set free. A saturated solution of the salt is also instantly and violently decomposed by strong aqueous ammonia. Oxygen has no effect either upon the dry salt at 15° C., or at a red heat, nor upon its aqueous solution. Steam perfectly and rapidly decomposes the salt at an incipient red heat, setting free all its silver. No chemical change took place on passing either of the oxides of nitrogen over the salt in a state of fusion. By passing anhydrous hydrofluoric acid vapour over perfectly anhydrous and previously fused fluoride of silver, at about 60° Fahr., distinct evidence of the existence of an acid salt was obtained. This acid salt is decomposed by a slight elevation of temperature. Numerous experiments were made to ascertain the behaviour of argentic fluoride in a state of fusion with chlorine, and great difficulties were encountered in consequence of the extremely corrosive action of the substances when brought together in a heated state. Vessels of glass, platinum, gold, charcoal, gas carbon, and purified graphite were employed. By heating the salt in chlorine, contained in closed vessels, formed partly of glass and partly of platinum, more or less corrosion of the glass took place; the chlorine united with the platinum and fluoride of silver to form a double salt, and a vacuum was produced. By similarly heating it in vessels composed wholly of platinum, the same disappearance of chlorine, the same double salt, and a similar vacuum resulted. Also, by heating it in vessels composed partly of gold, an analogous double salt, the same absorption of chlorine and production of rarefaction was produced. And by employing vessels partly composed of purified graphite, a new compound of fluorine and carbon was obtained.

"Approximate determinations of the Heating Powers of Arcturus and α Lyræ." By E. J. Stone.—About twelve months ago the author began to make observations upon the heating-power of the stars. At the February meeting of the Royal Astronomical Society he first became aware of what Mr. Huggins had done upon this question: his arrangements, however, did not appear to the author to meet the difficulties. After some trials, he arranged his apparatus in the following novel manner:—He uses *two pairs* of plates of compounds of antimony and bismuth. The areas are about $(0\cdot075)^2$ inches, and their distance is about 0·25 inch. The poles are joined over in opposite directions to the terminals of the pile and galvanometer. The whole pile is screwed into a tube of one of the negative eyepieces of the great equatorial. This completely shuts the pile up in the telescope-tube. A thick flannel bag is then wrapt over the eyepiece and terminals. The bag is prevented from actually touching the case of the pile, and is useful in preventing the irregular action of draughts upon the case of the pile and terminals. The wires are led from the terminals of the pile to the observatory library. The two faces of the pile are so nearly alike, that the currents which are generated by any equal heating of them are exceedingly feeble. The telescope is first directed so that the star falls between the two faces, and allowed to remain thus until the needle is nearly steady at the zero. The star is then placed alternately upon the two faces, and the corresponding readings of the galvonometer taken as soon as the needle appears to have taken up its position, which usually takes place in about ten minutes. The author next referred to the way in which he refers his results to those produced by independent sources of heat at known distances. The mean result of the observations on two nights is 0°·0198 F., as a measure of the heating effect of Arcturus in raising the temperature of the plate of antimony and bismuth when the heat is condensed by the object-glass of 12·75 inches. The direct effect without object-glass would be 0°·000000685 F. The author had not yet determined the coefficient of absorption for the object-glass, but if it be provisionally taken at $\frac{2}{3}$, the direct heating effect of Arcturus = 0°·00000127 F. The result may be otherwise stated as follows:—That the heat received from Arcturus is sensibly the same as that from the face of a Leslie cube containing boiling water at 383 yards. In the case of α Lyræ the heating power is = 0°·0088 F. This result is so much smaller than those obtained from Arcturus, although the observations of Arcturus were made under more unfavourable circumstances, that the author cannot but regard it as a fact that the star Arcturus does give us more heat than α Lyræ—a result probably due to the same cause which gives rise to the difference in colour between these stars, viz., the greater absorption of the red end of the spectrum in the case of α Lyræ than in the case of Arcturus. He mentioned that on June 25, 1869, he made a comparison between Arcturus and α Lyræ. The result gave for the heat received from Arcturus: to that from α Lyræ : : 3 : 2; but on account of the observations of α Lyræ having been interrupted by cloud, they were not, however, sufficiently numerous to eliminate mere errors of reading. From these observations the author concludes that Arcturus gives to us considerably more heat than α Lyræ; that the amount of heat received is diminished very rapidly as the amount of moisture in the air increases; that nearly the whole heat is intercepted by the slightest cloud; that as first approximations, the heat from Arcturus, at an altitude of 25°, at Greenwich, is about equal to that from the cube containing boiling water at a distance of 383 yards. The heat from α Lyræ at an altitude of 60° is about equal to that from the cube at a distance of 860 yards. The form given to the pile appears likely to be useful in many inquiries respecting differences of heating power.

Ethnological Society, January 11.—Dr. Richard King in the chair. Col. Lane Fox read a note on the use of the mere or pattoo-pattoo of New Zealand, in which he showed that this weapon is used as a thrusting-instrument, and should not, therefore, be referred to the type of the club. He regards it as having had its origin from the stone celt, since a series of transitional forms may be traced connecting the two implements. The author's opinion on the use of the mere was supported by a letter from the Rev. J. W. Stack, of Kaiopoi, communicated to Dr. Hooker, C.B., in which the writer explained that the mere was always used for thrusting and not for striking.—A communication was read from Dr. Haast, F.R.S., on some stone implements discovered in Bruce Bay, New Zealand. A polished stone chisel and a sharpening-stone were found by a party of miners in an auriferous "lead." Advancing inland from the present shore of the bay, several distinct belts of land may be observed, each characterised by peculiar vegetation; and it was in the fourth belt, at a distance of 525 feet from the present high-water mark that these implements were found. They are now deposited in the Canterbury Museum, N.Z. Although these polished implements are much more highly finished than are the roughly-chipped implements hitherto found in or near moa-ovens, the author does not venture to express an opinion on the relative antiquity of the two types: indeed, he considers it probable that they may have been used simultaneously by two races co-existing in the islands—the more highly-civilised using polished tools and dwelling near the coast, while the inhabitants of the interior retained the use of roughly-chipped implements, and followed the dinornis as it retreated inland. Mr. Bonwick referred to the great antiquity of these gold-bearing terrace-deposits.—At the same meeting Dr. Gustav Oppert read a paper on the Kitai or Kari-kitai. These are a small race of about 50,000 persons, dwelling near the Caspian Sea in the Russian province of Derbend, and in the Siberian district of Guldja. They are the descendants of a race which once ruled over China and Central Asia. One of their great princes, Yelintashe, was identified by the author with the celebrated Prester John or Presbyter Johannes. Dr. Oppert referred to the use of the names of metals by the Tatars as proper names and titles of dynasties—such as the Iron dynasty, Golden dynasty, &c. According to their own historical records, the Tatars had come from a district abounding in gold and iron. Dr. Hyde Clarke contrasted the valuable philological arguments brought forward in the present paper with the frivolous mode in which comparative philology is often employed. He alluded to the ethnological cause of the decline of the great empire of the Kitai, and referred it to the inability of any small dominant race to hold in subjection a large population composed of mixed races.

Royal Microscopical Society, January 12.—The Rev. J. B. Reade, F.R.S., president, in the chair. Mr. J. Browning read a paper on a new mode of measuring spectra bands. Mr. Browning described an adaptation, by himself, of the micrometer screw to the microscope, which afforded an easy and accurate method of measuring the bands of the absorption spectrum, and the invention was accepted as a valuable improvement on the method hitherto employed for the purpose.—Mr. W. S. Kent, F.Z.S., of the British Museum, read a paper on "the *Calcareous spiculæ* of the *Gorgonaceæ*, their modification of form, and the importance of their characters as a basis for genuine and specific diagnosis." This paper was illustrated by an elaborate series of drawings of the animals and the spicula of the various species.—In consequence of the time occupied by the reading of the previous papers, a contribution from Mr. A. Sanders, M.R.C.S., "On an undescribed stage of development of *Tetrarhynchus corallatus*" was taken as read.

DUBLIN

Royal Irish Academy, January 10.—Sir Robert Kane in the chair. The Rev. Dr. Dickson read an account of some portions of the "Ars moriendi," preserved in the manuscript room of the College Library, and compared it with the photographs of the perfect copy of this work in the collection of Herr Weigel, of Leipsig. It is an excellent specimen of block-printing. The fragments in the library appear to have been portions of an early printed volume, as well as of one printed with great care, and belonged to the edition in small folio of twenty-four leaves printed on the one side.—Dr. John Barker read a paper on the "illumination of microscopic objects." One of the most important improvements of late years in object-glasses of high powers has been the immersion of objectives of a particular construction into a film of water placed on the glass covering the object, whereby it is found that the definition, light, magnifying power, and working distance are each much increased. The object of the paper was to show how the present principle could be applied with great advantage to the general illumination of objects. The results of some experiments were then detailed. Wenham's paraboloid was altered as follows: the tip was ground flat, and a film of water was introduced between it and the under surface of the glass slide containing the object, free action of the stage movements being thus allowed, and no light was lost. This form of illumination is suitable to all kinds of axial illumination, though it is but right to add that it has only practically been tried in a form corresponding to Wenham's paraboloid. Details of the construction of the paraboloid, its size, and curvature were given; and the paper concluded by the author claiming for this mode of illumination the following advantages:—1. Objects are seen by light reflected from their surfaces, and, if transparent, from their interiors. 2. No disturbing light impinges on the retina. 3. All shadows are avoided. 4. The oblique rays of light are economised. 5. The light is purely achromatic. 6. The interior of partially transparent objects can be lit up. 7. Definition is improved. 8. It is easy of application; and, lastly, it is not expensive.—Dr. Stokes presented, on behalf of W. T. De Visme Kane, Esq., a large stone celt found in Ireland. A copy of the second volume of the "Brehon Laws," just published, was laid on the table. The following were elected members:—W. Archer, Professor R. Ball, R. Day, Sir T. Esmonde, Bart., T. A. Jones, Rev. J. P. Mahaffy, and J. P. O'Reilly.

PARIS

Academy of Sciences, January 10.—M. Delaunay communicated a memoir on the physical constitution of the moon, and Father Secchi one on the constitution of the solar corona, and some peculiarities presented by rarefied gases when rendered incandescent by electric currents: we shall return to these papers.—M. Becquerel presented the second part of his eighth memoir on electro-capillary phenomena, in which he treats of the muscular, nervous, and other currents.—M. E. Becquerel communicated a note on the determination of weak electromotor forces, in which he described a method of determining the amount of force developed in organic bodies and their parts.—M. Piarron di Mondesir communicated the second part of his paper on a new method for the solution of problems in mechanics, and M. Verdeil a note indicating two experiments to be made, by means of the pendulum, to determine the variation of the resistance of the air with the velocity.—A discussion on the proposed demonstration of Euclid's postulate of parallel lines, by M. Bertrand, was raised by the opening of a sealed packet deposited by M. Lionnet on the 27th December last. M. Boillot maintained that it is impossible to get rid of the idea of infinity when we attempt to demonstrate Euclid's postulate; and M. J. Hoüel, the impossibility of demonstrating the principle of the theory of parallels by means of a plane figure. M. Fuix called the attention of the meeting to a demonstration of the postulate, independent of the idea of infinity given by him in a published work.—In a memoir on nitrous acid by M. E. Frémy, the author stated that pure nitrous acid dissolves without decomposition in a great excess of cold water, but that it is split into nitric acid and deutoxide of nitrogen by the addition of pulverulent bodies. He also referred to the reducing properties of nitrous acid, and to its behaviour and modification by substitution under the influence of hydrogenated bodies.—MM. Odet and Vignon presented a paper on the action of dry chlorine upon dry nitrate of silver, in which they described an experiment confirming their previous supposition that in the preparation of anhydrous nitric acid by this means, the reaction combines two phases, namely: 1. Production of chloride of azotyle with evolution of oxygen; and 2. Reaction of the chloride of azotyle upon the excess of nitrate of silver.—A memoir was also presented by M. A. Boillot, on the synthesis of hydrosulphuric acid by exposing flowers of sulphur to the action of the electric spark in contact with hydrogen; and one by M. T. Schlœsing, containing analyses of the mineral contents of the waters of arable lands.—M. Feil addressed a reply to a previous note by M. Gaugain on the manufacture of artificial gems; and MM. A. Riche and P. Champion a memoir on the manufacture of tom-toms and cymbals.—Of biological papers only few were communicated, the chief one being a continuation of M. Lacaze-Duthier's researches upon the morphology of the Mollusca, in which the author treats of the *Lamellibranchiate Acephala*, or ordinary bivalved molluscs.—M. Colin discussed the question whether there is any relation between the intelligence of animals and the development of the nervous centres, and showed by numerous tables that there is no exact relation between the size of the encephalon and the observed intelligence.—M. Bergeon noticed the purpose of the lachrymal glands, which he considered to be chiefly the moistening of the air passages, and of the air passing through these to the lungs, so that they are really connected with the function of respiration.—M. Drouyn de Lhuys communicated an extract from a letter noticing the attacks of an *Acarus* upon the grape-vines at the Cape of Good Hope. The parasite is said to live upon the roots, and between the bark and wood of the plants.

VIENNA

Imperial Academy of Sciences, December 9, 1869.—Dr. L. J. Fitzinger communicated the first part of a critical revision of the Rhinolophous family of Bats. It treated of the genera *Cœlops*, *Phyllorhina* and *Asellia*.—Director Tschermak presented a memoir on the form and composition of the Felspars.—Dr. J. Peyritsch communicated a memoir on abnormities of structure in the Umbelliferæ, containing the description of a series of malformations of the flowers in *Carum Carui*, *Daucus Carota*, *Torilis anthriscus*, and *Peucedanum Chabræi*.—In connection with these the author discussed the axial or carpellar nature of the fruit of the Umbelliferæ, and remarked that such cases show that the distinction between leaf and axis is not well founded in nature.—M. Schrauf noticed the occurrence of Brookite in iron-glance from Piz Cawradi, to the south of Chiamut in the Tavetsch valley of Graubündten.—The table of observations at the Central Meteorological Observatory, for the month of November, was communicated.

December 16, 1869—Professor Reuss communicated a memoir by Dr. Manzoni "On the Italian Fossil Bryozoa," in continuation of previous papers by the same author. The present paper related exclusively to the genus *Lepralia*, of which the author described and figured 21 species, 15 of them as new forms. Of the species described, 12 are from the middle miocene of Turin, 4 from the middle pliocene of Castelarquato, and the remaining 5 from the upper pliocene of the neighbourhood of Reggio in Calabria.—Professor A. Winckler presented a memoir on some formulæ and methods relating to the theory of definite integrals.—Dr. Tiele, of Bonn, and Dr. T. Oppolzer communicated statements of the elements of Comet III., 1869, and the latter a memoir on the determination of the path of a comet.—Professor E. Hering presented a first memoir on the influence of respiration on the circulation of the blood, in which he maintained that the system of the vasomotor nerves experiences a periodic innervation by the respiratory nervous centre, which causes periodic contractions of the muscular coat of the vessels. These he regarded as respiratory movements of the vascular system.—Dr. F. Steindachner communicated the second portion of his memoir on the Fishes of the Senegal, in which he described the species (28 in number) belonging to the families Gobiidæ, Mugilidæ, Gerridæ, Chromidæ, Anabatidæ, Pleuronectidæ, and a part of the Siluridæ. Four of these were described as new, namely: *Eleotris senegalensis*, *daganensis*, and *Lebretonis*, and *Mugil Dumerili*. The first two belong to Bleeker's sub-genus *Culius*, the previously known representatives of which occur in the Indian Ocean and Polynesia. The author regarded *Chromis mossambicus* (Peters) as specifically distinct from *C. niloticus*, *Hemichromis bimaculatus* and *auritus* (Gill), and *H. guttatus* (Günther) as varieties of one species, *Chrysichthys acutirostris* (Günther) as identical with *C. nigrodigitatus* (Lac.), and *Gerres octactis* (Bleeker) with *G. melanopterus* of the same author.

BERLIN

German Chemical Society, January 10. — The following papers were read:—Wichelhaus, "On a base isomeric with cyanide of ammonium." By the action of the tribasic formic ether $CH(OC_2H_5)_3$ on acetamide $NH_2C_2H_3O$, a base of the following composition, $CH.NC_2H_3O.NHC_2H_3O$, was obtained. This substance is converted by water into the acetate of the new base $CH.NH.NH_2$. The latter is a volatile liquid, yielding crystallised salts.—Philipp, "On perchloride of iodine;" Hansen, "On the ethylides of thallium;" P. W. Hofmann, "On the manufacture of sulphuric acid." The author, who is at the head of the manufactory of Dienze in France, accounts for the loss of oxides of nitrogen in the manufacture of sulphuric acid, by proving that these oxides are partly reduced to nitrogen, when the sulphuric acid in the lead-chambers sinks below a certain strength. The loss can therefore be avoided by carefully regulating the steam admitted into the chambers.—Schoras, (1) "On the influence of sunlight on the reduction of metallic chlorides through oxalic and tartaric acids;" (2) "On the colorisation of dry platinocyanides through traces of moisture."—Friedel and Ladenburg, "On silicopropioxic acid;" Tieman, "On derivatives of guanidine;" Junning, "Mechanical explanations of chemical reactions;" Schuchard, "On the preparation of zirconium."

BONN

Lower Rhenish Society for Natural and Medical Science—*Chemical Section*, November 13. — Professor Binz exhibited a new body, "Dihydroxylchinin," obtained by G. Kerner from quinine by treating the latter with potassic permanganate. It gives all the reactions of the alkaloid, but differs from it amongst other things in the want of basic properties and the absence of influence on the organ of taste. It likewise differs from it essentially in its physiological properties, being entirely indifferent even in large doses. Dr. Zinke gave an account of new synthesis of aromatic acids. He has obtained phenyl-acetic acid from Monochloroacetic acid, and brombenzol by treatment with finely-divided silver. Professor Kekulé communicated the results of some experiments of Dr. Thorpe, showing that bromine free from iodine enters the ethyl-group of ethylbenzole even at a low temperature, and that from the bromide thus formed various derivatives can be obtained, some of which have already been proved by Berthelot. Dr. Budde gave a preliminary report on his researches on the electric conductivity of hydrogen, oxygen, and nitrogen, at various pressures. His results agree most nearly with those of Faraday, and show a greater decrease of resistance than of pressure.

November 27.—Dr. Muck communicated his recent researches on the formation of manganic sulphide from various manganese salts and various soluble sulphides.—Professor Rhitthausen likewise made some communications on the occurrence (not hitherto observed) of amygdaline in vetch seeds.

DIARY

THURSDAY, JANUARY 20.

ROYAL INSTITUTION, at 3.—On the Chemistry of Vegetable Products: Prof. Odling.

ROYAL SOCIETY, at 8.30.—On the Mechanical Performance of Logical Inference: W. Stanley Jevons.—Preliminary Paper on certain Drifting Motions of the Stars: R. A. Proctor.—On Jacobi's Theorem respecting the relative Equilibrium of a Revolving Ellipsoid of Fluid, and on Ivory's Discussion of the Theorem: J. Todhunter, F.R.S.

LINNEAN SOCIETY, at 8.—On the Flora of Iceland: Prof. Babington.—On New British Spiders: Rev. O. P. Cambridge.

ZOOLOGICAL SOCIETY, 8.30.—Descriptions of a new genus and of eighteen new species of Land and Marine Shells: Henry Adams.—On the genus Pelargopsis of the family Alcedinidæ: R. B. Sharpe.—Description of a new Fish from the vicinity of Aden: Lieut.-Colonel R. L. Playfair.

CHEMICAL SOCIETY, at 8. ANTIQUARIES, at 8·30.

NUMISMATIC SOCIETY, at 7.

FRIDAY, JANUARY 21.

ROYAL INSTITUTION, at 3.—On Haze and Dust: Professor Tyndall.

PHILOLOGICAL SOCIETY, at 8.15.

SATURDAY, JANUARY 22.

ROYAL INSTITUTION, at 3.—On Meteorology: Mr. Scott.

ROYAL BOTANIC SOCIETY, at 3.45.

MONDAY, JANUARY 24.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.

ENTOMOLOGICAL SOCIETY, at 7.—Anniversary Meeting.

LONDON INSTITUTION, at 4. MEDICAL SOCIETY, at 8.

TUESDAY, JANUARY 25.

ROYAL INSTITUTION, at 8.—On the Architecture of the Human Body: Prof Humphrey.

ETHNOLOGICAL SOCIETY, at 8.—On the Origin of the Tasmanians, geologically considered: J. Bonwick.—On a Frontier-line of Ethnology and Geology: H. H. Howorth.—The Nicobar Islanders: G. M. Atkinson.

INSTITUTION OF CIVIL ENGINEERS, at 8.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY, at 8.30.

WEDNESDAY, JANUARY 26.

SOCIETY OF ARTS, at 8.—On the Modes of Reading in Use by the Blind, and the Means for arriving at Uniformity: Thomas Armitage, M.D.

GEOLOGICAL SOCIETY, at 8.—On the Crag of Norfolk and associated Beds: Joseph Prestwich, F.R.S., F.G.S.—On the Fossil Corals of the South Australian Tertiary Deposits: Dr. P. Martin Duncan, F.R.S., Sec. G.S.—Note on a very large undescribed Wealdean Vertebra: J. W. Hulke, F.R.S., F.G.S.

ARCHÆOLOGICAL ASSOCIATION, at 8.

BOOKS RECEIVED

ENGLISH.—The Year-book of Photography for 1870: G. W. Simpson (Piper and Carter).—The Bible in India: Louis Jacolliot (J. C. Hotten).—The Body and its Health: E. D. Mapother, M.D. (Simpkin, Marshall and Co).—Natural Phenomena and Chronology of the Seasons, Part I.: E. J. Lowe, F.R.S. (Bell and Daldy).—Journal of the Statistical Society.—The Geology, Botany, and Zoology of the Neighbourhood of Alnwick: G. Tate (H. Hunter).

FOREIGN.—Note sur les Surcharges à considerer dans les Calculs des Tabliers Metalliques: M. L. Leygue.—Chênes de l'Amerique Tropicale.—Compendium der Physiologie des Menschen: Julius Budge.—Untersuchungen aus dem Physiologischen Laboratorium in Würzburg: R. Gescheidlen.—Die Praktische Markscheidekunst: E. Borchers.—Industries anciennes et moderne de l'Empire Chinois: Paul Champion.—Annales des Sciences Géologiques: Hébert et Alph. Milne-Edwards.—Cours Elémentaire de Mecanique Theorique et Appliquée: Ch. Delauny.—Cours Elémentaire d'Astronomie: Ch. Delaunay.—Recherches sur l'Ancienneté de l'Homme dans les Grottes et Monuments Megalithiques du Vivarais: J. Ollier de Marichad—Berliner Astronomisches Jahrbuch für 1872: W. Förster.—Handbuch der Chemischen Technologie: P. A. Bolley.—Ueber die Altesten Formen des Organischen Lebens: Ferd. Roemer.—Ueber den Parasitismus in der Organischen Natur: Maximilian Pertz (through Williams and Norgate).

CONTENTS

ERRATA.—Page 238, second column, line 34 of footnote: for "habitude" read "hebetude."—Page 289, second column, line 37: for "rectorial" read "vectorial."

Every Thursday, in royal 8vo. price 4d., and in Monthly Parts, price 1s. 4d. and 1s. 8d.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

"*To the solid ground*
Of Nature trusts the Mind that builds for aye."—WORDSWORTH.

THE object which it is proposed to attain by this periodical may be broadly stated as follows. It is intended:

FIRST, to place before the general public the grand results of Scientific Work and Scientific Discovery, and to urge the claims of Science to a more general recognition in Education and in Daily Life;

And, SECONDLY, to aid Scientific men themselves, by giving early information of all advances made in any branch of Natural knowledge throughout the world, and by affording them an opportunity of discussing the various Scientific questions which arise from time to time.

To accomplish this twofold object, the following plan is followed as closely as possible.

Those portions of the Paper more especially devoted to the discussion of matters interesting to the public at large contain:

I. Articles written by men eminent in Science on subjects connected with the various points of contact of Natural knowledge with practical affairs, the public health, and material progress; and on the advancement of Science, and its educational and civilizing functions.

II. Full accounts, illustrated when necessary, of Scientific Discoveries of general interest.

III. Records of all efforts made for the encouragement of Natural knowledge in our Colleges and Schools, and notices of aids to Science-teaching.

IV. Full Reviews of Scientific Works, especially directed to the exact Scientific ground gone over, and the contributions to knowledge, whether in the shape of new facts, maps, illustrations, tables, and the like, which they may contain.

In those portions of "NATURE" more especially interesting to Scientific men are given:

V. Abstracts of important Papers communicated to British, American, and Continental Scientific societies and periodicals.

VI. Reports of the Meetings of Scientific bodies at home and abroad.

In addition to the above, there are columns devoted to Correspondence.

LIST OF CONTRIBUTORS.

ABEL, F. A., F.R.S., *H.M. Chem. Dep. Woolwich.*
AGASSIZ, PROF. L., *Museum of Comparative Zoology, Harvard College.*

DUST AND DISEASE

PROFESSOR TYNDALL'S lecture last Friday night at the Royal Institution, which we give *in extenso* in another column, has excited unusual interest, not only on account of the Professor's beautiful demonstration of the presence of organic dust in our London atmosphere, but from the manner in which he has sought to connect this presence with certain theories of disease held by part of his audience.

The revelations made by an ordinary sunbeam passing through a hole in the shutter are familiar enough; and the changes produced on the beam by a candle flame or a red-hot poker (an experiment used long ago by Dr. Wollaston for another purpose) will show in a rough manner the nature of the investigations.

Their practical result may be thus stated: London air contains a large amount of organic particles powerfully reflecting a light thrown upon them; and these particles cease to reflect light when the air containing them is submitted to the action of a high temperature, or when it is passed through a strainer or filter. Some of the appearances produced by certain modifications of the experiments are striking. Such, for example, as the disappearance of reflected light when air of a temperature below the incandescent point is made to rise through the beam showing the dust; or when certain gases are used instead of warmed air. In these cases the reflection of light from the dust particles disappears, and blackness takes its place. We are not, however, convinced that the Professor's explanation of this striking phenomenon is quite tenable. It presupposes a rapidity in the gas and air currents greater than can be followed by the more sluggish dust particles; so that these are left behind, or thrown to one side, and the rarefied air or gas deprived of dust particles enters the beam, and becomes invisible from absence of reflecting particles.

One would suppose that, sooner or later, the particles must follow the air in which they float, unless the heated air or gas become so much lighter than the particles that the latter will tend to fall downwards. This point, however, is one which admits of further demonstration.
